LUMBAR ANESTHESIA.

LUMBAR ANESTHESIA has found great favor in Germany, surgeons of such standing as Bier, v. Rosthorn, Witzel, and Sellheim using it continuously in their practice, and studying the value of the various modifications of the methods, as well as of the drugs used in this connection. The amount of material observed may be judged from an article by Dr. Holzbach in the *Münchener medizinische Wochenschrift* for July 14, 1908, which gives the experience obtained from over one thousand lumbar anesthesias, two-thirds of which were employed for the performance of laparotomies. Holzbach says that the following points must be fulfilled by any anesthesia, whether local or general: Absolute freedom from pain during the whole duration of the operation; such effect upon the tissues of the operation field that the technique of the procedure is rendered as easy as possible; the smallest possible danger from the use of the anesthetic during and after the operation; the absence of unpleasant sensations at the beginning of the anesthesia and following it; the least possible influence upon the postoperative course of the disease.

So far as the first requirement is concerned, lumbar anesthesia is not as reliable as inhalation narcosis, in every case of which complete freedom from pain may be promised to the patient. Of some 250 specially studied cases, in nine lumbar anesthesia proved to be a complete failure, in a few others the course of the operation was disturbed, in still others, amounting to 16.4 per cent., ether or chloroform had to be used to complete the narcosis begun by the lumbar injection. The second condition is fulfilled by the newer method of narcosis much better than by the old; muscular relaxation is much earlier attained and the involuntary spasms of the diaphragm affecting the contents of the peritoneal cavity are very seldom observed in lumbar anesthesia. Moreover, the surgeon need no longer divide his attention between the operation itself and the anesthesia; there is no occasional choking, no vomiting, no falling back of the tongue, no such danger of sudden death from paralysis of the respiratory center. On the other hand, various trophic disturbances, transitory albuminuria, even inflammation of the kidneys, obstinate pain in the head and neck are still quite frequent sequences of lumbar anesthesia, though with the improvement in technique they are observed much more rarely than formerly. So far as freedom from unpleasant sensations and feelings in the beginning of the narcosis is concerned, the use of morphine in connection with the anesthesia allows the attainment of this end in either type of narcosis. As this seems to be less dangerous in the case of lumbar anesthesia than with the use of ether or chloroform, which of itself has a dangerous effect upon the respiratory and circulatory centers, the former method enjoys some advantage over inhalation anesthesia. The postoperative course, the last point considered by Holzbach, is certainly less disturbed in the case of lumbar narcosis; vomiting is extremely rare, lung complications are also infrequent, and the patient may be allowed to leave the bed in much shorter time than is usual with the employment of ether or chloroform. The one desideratum, according to Holzbach, is the care in the details of the technique of producing spinal anesthesia, and to obtain this, one who has made a special study of the art and practice of this field of medicine should be called upon to perform the work. The latter suggestion applies to inhalation narcosis, perhaps, as much as to the newer method of anesthesia. The technique of inhalation narcosis is, however, so much simpler than the puncture of the spinal canal required in the production of lumbar anesthesia, that the former method will always be preferred in emergency work and in those hospitals where the untrained internes are required to administer the anesthetic.

How far the newer method will supplant the old in selected cases and in the presence of special arrangements for its successful use remains to be seen. In a private letter from Berlin it is stated that general narcosis with ether or chloroform has almost entirely been given up in the clinics under the direction of Professor v. Bier, lumbar narcosis or local anesthesia produced by intravenous injections of narcotics being used; the advantages claimed for the latter methods are such as to warrant a trial by American surgeons on a more extensive scale, so that they may decide for themselves how applicable it is to the different conditions which govern surgical practice on this side of the ocean.

THE INTERNATIONAL LANGUAGE QUESTION.

THE holding of the first American Esperanto conference at Chautauqua a few weeks ago has directed attention anew to the ever-present problem of an international language. The question is one that interests everyone—the business man, the scientist, the traveler, the millionaire with marriageable daughters—in fact, all who have or hope to have business or social relations with persons speaking another language than their own. The need of a common medium for the communication of ideas will be emphasized again next month when the International Tuberculosis Congress meets in Washington. There will be speakers in French, German, English, and perhaps other languages, and what they say will be understood fully by some, more or less imperfectly by some others, and not at all by a great many. How much more fruitful the addresses and discussions would be if every member of the Congress, no matter what his native tongue, had a fluent use of some language common to all and this language was employed exclusively in all the scientific work of the meetings, is something that needs no argument.

There is and can be no dispute as to the desirability of a world language supplementary to the national idiom of each country; the only question is as to the choice of this common tongue.

There is hardly a language spoken by civilized people on the face of the earth, not to mention the one hundred and fifty or more artificial languages that have been invented during the past two centuries, that has not been proposed at one time or another for adoption as this supplementary speech. Latin once held this place, and five hundred years ago educated men could communicate through this medium freely and intelligibly, orally or in writing, with their fellows in any part of Western Europe. Later French, the lingua franca, became the universal language of polite society and diplomacy, but this, too, has lost its supremacy, and Babel reigns once more. The claim is frequently made, by those whose vernacular it is, that English is making rapid headway as an international speech, but this is true to the extent only that it is the native tongue of a constantly increasing number of the inhabitants of the earth. A business man in England, or North America, or Australia, may address his foreign correspondents in English, but nine times out of ten they will reply in German, or French, or Spanish; and the scientist who would keep himself informed of progress in his special branch must have a reading knowledge at least of two or three languages other than his own.

There is no living language that would not serve the purpose of international communication if universally taught, the question of relative ease or difficulty of acquirement being entirely negligible if the language were learned in infancy at the same time and in the same way as the mother tongue and its use were continued in the school curriculum in the teaching of history and of physics, chemistry, and the other scientific branches. The problem is then to select from among the living tongues the one best adapted to the purpose, irrespective of its difficulty or ease of acquisition by adult students—which is more apparent than real if the study be approached in the proper way—or of the number of persons now speaking it.

The choice should be of a living language. A return to Latin is still advocated by a few enthusiasts. But Latin is dead—as dead as the Cæsar who glorified himself in it. In spite of the efforts of those who would modernize it and adapt it to the needs of expression of the twentieth century man of science or of business, the tongue is too stiff for modern use. Moreover, it lacks the authority which only every-day use, by those who possess it as their own, and a living modern literature can give it. The choice should be also of a real language. The objection of the lack of authority applies with equal, if not greater, force to an artificial language that it does to Latin. Latin at least has a literature, unsuited as it may be as a model for present use, by which irregularities and unwarranted neologisms might be in a measure checked, but Esperanto, the only artificial language now claiming recognition, has none, save a few good and many bad translations and the ephemeral articles in its periodical publications. It has, moverover, what impresses many of its students as the fatal defect of being a mere Frankenstein creation, related to nothing else in the world and void of an informing soul. It is, indeed, a wonderful creation, and admirable as a linguistic *tour de force;* it is logical in its formation and comparatively easy for adults to learn—to read, and many who have progressed thus far are vociferous in its praise. There are, nevertheless, many defects in its construction, and already a quarrel is hatching between the would-be reformers and the "stand-patters" in Esperantism. This is the rock on which Volapük split at a time when it seemed to be almost on the point of acceptance by the business world, and until Esperanto has weathered this storm, if it does, its adoption as a world language does not seem advisable or likely.

The choice should be of a language, if such there be, that is already universal in its root-forms and a part of the speech of the entire civilized world. There is such a language—the Greek. Not only is Greek the basis of the vocabulary of every science, it is constantly on the tongue of the business man, the society woman, even the school child—sadly twisted and shamefully maltreated oftentimes, even by the man of scientific education, but still Greek. The root is there and ready to send up its branches and blossom forth into the flower of a beautiful speech if only cultivated. For twenty years the Medical Record has held that this incomparable language was the one best fitted for use as the world language of science; and it is equally adapted for commercial and other purposes. It is the second language, when not the first, of all the dwellers on the eastern Mediterranean shores from the Piræus all the way to Alexandria, and it answers perfectly the needs of these eminently commercial peoples. This is not the Greek of Homer, of course, nor even that of the New Testament, but the Greek of the cultivated people of Athens and Constantinople and Smyrna. It differs but little from the so-called ancient Greek—no more than, if as much as, the English of Chaucer or Spenser does from the English of to-day; but what difference there is, is all on the side of simplicity. It is less difficult to learn, even for an adult, than French or German, and if it were taught in all the elementary schools of the world as a living tongue, not as an exercise for translation merely, the coming generation would use it as fluently and as naturally as it would the national speech.

The suggestion to adopt modern Greek as a second tongue for all the nations of the civilized world is not novel; it was made by Voltaire even at a time when his own French was the language of the Prussian court and was almost an international tongue. Before and since his day other men of practical experience in the work of the world have made the same suggestion, which is, indeed, one worthy of the consideration of those who recognize the necessity of a common medium of communication and who are tempted to turn to Esperanto in ignorance of anything better. But even Esperanto, or Volapük, or Chinese, would be better than nothing, for the impediment to the diffusion of knowledge and the crippling of business which the lack of a world language causes are very real and lamentable.

PASTEURIZATION OF MILK IN GREAT BRITAIN.

Much difference of opinion exists even yet among medical men regarding the pasteurization of milk. It is conceded that the method when properly carried out destroys most of the harmful germs of milk, but it is contended by the opponents of pasteurization that although the process is so far effective, at the same time it affects injuriously the nutritive qualities of milk. Medical authorities in this country do not look on pasteurization with the disfavor with which it is generally regarded by their British confrères. Here the view held by the majority of physicians may be said to be that pasteurization is the lesser of two evils, that it is better that young children should drink the milk thus treated, albeit it may not be so nourishing as is the same food in a natural state, rather than to be fed on contaminated milk. It must be borne in mind that in cities in hot weather it is virtually impossible for poor persons to obtain a clean milk.

In England, however, where prejudice against pasteurization is still widespread, there appear to be signs that medical opinion is changing in this respect. Mr. Henry Kenwood, professor of hygiene in the University of London, and one who should understand his subject thoroughly, believes in pasteurization; at least, he thinks it is wiser to feed infants and young children on milk which has undergone this form of purifying by heat than to give them raw milk, in most instances full of germs more or less noxious. He broadly defines pasteurization as the exposure of milk, previously cleansed by filtration or centrifugalization, to a temperature not exceeding 70° C. for a short period; and then its rapid cooling to a temperature as much below 16° C. as possible. He holds that under such conditions it is possible (1) to reduce the microorganisms which are capable of being cultivated on artificial media to less than 5 per cent. of those which can be cultivated from the original milk and thereby to destroy or inhibit the fermentation bacteria so as to delay the natural souring of the milk some twenty-four hours or longer, the milk meanwhile keeping perfectly wholesome; (2) to destroy the specific organism of tuberculosis, diphtheria, typhoid fever, cholera, and dysentery, and, doubtless also in large measure, those organisms that are causal of diarrhea; (3) to do away with the necessity for drugging the milk with harmful chemical preservatives. Mr. Kenwood holds decided views as to the dangers incurred by feeding children on pasteurized milk, and feels convinced that such dangers have been greatly overrated. He states that the available evidence goes to show that pasteurized milk very rarely causes infantile scurvy, that the physical changes brought about by the process are practically nil, that digestibility is increased. He is, of course, in favor of using every possible means to ensure a milk supply clean from the source, and of employing every effort to transport, distribute and deliver it uncontaminated, but holds that in England, at any rate, such an ideal state of affairs is still far away. It may be said that there are many medical men of note in Great Britain who, while perhaps not going quite so far as Prof. Kenwood in their advocacy of pasteurization, nevertheless agree in the main with his views. Mr. Nathan Straus has established depots for pasteurizing milk in various large British cities and has given great impetus to the movement.

Syphilis and Tabes Dorsalis.

The relation of locomotor ataxia to syphilis has been recently studied with the help of the Wassermann method of demonstrating syphilitic antibodies in the fluids of the organism. The work is of practical importance, the demonstration of the antibodies being a sign that antiluetic treatment is still indicated; it is, at the same time, of the greatest theoretical interest, for it may solve the final significance of a syphilitic infection in the etiology of locomotor ataxia and of general paralysis, and thus decide whether these two diseases are parasyphilitic conditions only or may be caused by other etiological factors. Dr. Albert Schütze (*Zeitschrift für klinische Medizin*, Vol. LXV., Nos. 5 and 6) has examined one hundred patients in whom the clinical diagnosis of locomotor ataxia was made, using either the blood serum or the spinal fluid for the determination of the specific reaction for syphilitic antibodies. In sixty-nine patients such reaction was positive, showing the great value of the procedure in demonstrating that a syphilitic infection had taken place in the past, quite a few of the positive results being obtained in patients denying such infection. Only a few cases were examined before and after the specific treatment for syphilis, but all of these leave the impression that such treatment markedly diminishes the strength of the reaction; moreover, quite a number of cases with a history of protracted and thorough treatment for the infection in the past gave negative results in the examination for the specific reaction of syphilis, while those untreated or unsufficiently treated gave usually a very marked reaction; thus the specific value of the antisyphilitic treatment is corroborated by these laboratory findings. Of course, all of these observations are neither complete nor numerous enough to allow of final conclusions; sufficient work, however, has been done to prove that Wassermann's reaction for the antibodies of syphilis, if it is finally definitely proven to be specific, will be one of the most valuable results of the recent studies in immunity.

Operative Treatment of Sciatica.

Neuritis involving the sciatic nerve or its cords of origin is one of the most obstinate and trying affections, making an invalid of the patient in many cases and always interfering with his general physical and mental wellbeing. The host of remedies proposed in the treatment of the affection shows how little reliance can be placed upon any one of them in the individual case, natural remissions in this chronic disease having been often looked upon by some enthusiastic supporter of a special drug as the result of medication. Nerve stretching has been successful in many instances, and in the *Deutsche medizinische Wochenschrift* for July 16, 1908, Dr. Alfred Pers claims that the mere freeing of the nerve from adhesions to the surrounding tissues is curative, especially if practised in such place as the sciatic foramen, where adhesions may quickly result in undue pressure upon the nerve. The author had operated according to his method upon forty-three patients, thirteen of whom were completely incapacitated by the disease, while the remaining thirty could not walk without limping. His results

were certainly encouraging; prompt relief followed the operations, forty patients being cured of their trouble, both recent and old standing cases responding in a similar manner to the treatment. Three patients were later attacked with recurrence of symptoms, a percentage that is much lower than in cases in which stretching of the nerve has been the procedure chosen. The results after the operation are such as to lead the author to conclude that the neuritis is only of a slight grade in this affection; the chief lesion is a perineuritis, and the freeing of the nerve from adhesions is the most rational procedure in this pathological condition.

The Tuberculosis of Mammals and of Birds.

Ever since Koch's well known announcement that the bacillus of bovine tuberculosis is not pathogenic for man, the question of the relations between the three main varieties of tuberculosis, of man, of cattle, and of birds, has been warmly debated. In the *Centralblatt für Bakteriologie, etc.,* Band XLVI, Heft 6, Oluf Bang tells of his study of the behavior of mammals toward avian bacilli, and of birds toward the bacilli of mammalian tuberculosis. He succeeded in infecting healthy fowls with twelve species of tubercle bacilli derived from tuberculous horses, cattle, and men. Six other species could not be thus transferred. Thus 60 per cent. of the species of bacilli examined proved to be equally pathogenic for fowls and for mammals. Moreover, in most of these cases the author succeeded in showing that the mammalian tubercle bacilli after passing through the organism of the fowl assumed the characteristics of avian bacilli; they became morphologically similar to the latter, grew very pathogenic for fowls, and gradually diminished in virulence for guinea-pigs. The opposite experiments, those of infecting mammals with avian bacilli, were also successful in many cases, young animals proving to be especially susceptible to the action of the bacilli; it was, however, impossible to decide whether such bacilli underwent any metamorphosis into mammalian types in their passage through the bodies of mammals. In the light of this and other facts it seems justifiable to say that the burden of proof, at least, lies with those who deny the pathogenicity of bovine bacilli for human beings, or their capacity of being transformed into other types after passing through a different species of animals.

News of the Week.

City Hospital Reforms.—Two years ago Mayor McClellan appointed a committee of nineteen to investigate hospital facilities and administration in New York. This committee has just made its formal report. As regards the distribution of hospital facilities the commission gives the following figures: Manhattan, with 50 per cent. of the city's population, has 57 per cent. of the hospital beds. The Bronx, with 8 per cent., has 12 per cent. of the beds; Brooklyn, with 34 per cent., has 26 per cent. of the beds; Queens, with 5 per cent., has 3 per cent. of the beds, and Richmond, with 3 per cent., has 2 per cent. of the beds. A very general reorganization of the hospital system, so far as the city controls it, is recommended, together with its centralization and unification, and control and extension of the ambulance system. The point is made that with the present system the public hospitals are administered under three heads, the metropolitan and city hospitals under the Department of Charities, the hospitals for contagious diseases under the Board of Health, and Bellevue and the allied hospitals under a board of trustees. This, of course, is responsible for duplication and for omission, and for the lack of any definite policy to meet the growing needs of the city. The committee therefore recommends the establishment of a Department of Hospitals, to be administered by a Commissioner aided by an advisory board. All the public hospitals of the city and the entire ambulance service should be in charge of this department. Other recommendations are for the establishment of relief stations for the treatment of minor injuries, the establishment of a central ambulance bureau to receive all calls, a special service for the transfer of patients, city ownership of all ambulances and horses, and prompt extension of hospital facilities.

Tuberculosis Campaign.—Because of the success of the traveling tuberculosis exhibits which have been shown in many of the larger cities, the State Charities Association is now having prepared six educational exhibits which are to be sent on tours through New York State, with stops at thirty-six different county fairs. Many new features are to be included in these exhibits, on which experts have been at work for many months. Models of perfectly lighted and ventilated factories will be contrasted with models of sweatshops where the disease flourishes. Maps and diagrams showing the prevalence of tuberculosis in each county, pictures, and painted mottos will be displayed. In addition large phonographs will be employed, with records which will give important information, alternated with records of popular music. A missing-word contest is also to be included, with prizes sufficient to be attractive.

Tuberculosis Day Camp at Vanderbilt Clinic.—The Board of Managers of the Vanderbilt Clinic, New York, have decided to extend the work of the clinic by establishing a day camp on the roof of the clinic building for the use of tuberculous patients. Changes are now being made to permit of the utilization of the roof for this purpose, and it is hoped that the camp will be opened on October 1. The New York County Branch of the Red Cross has agreed to provide the funds necessary for the maintenance of the camp after it is constructed, and the executive work will be largely in the hands of the Women's Auxiliary Committee of the Vanderbilt Clinic, an organization recently formed to direct and assist in the work of the Department of Visiting Nursing, subject to the control of the physicians and managers of the clinic. The roof of the clinic is well adapted for the purposes of a day camp. The building is situated near the river and is considerably higher than those surrounding it, so that to the west a clear sweep is obtained. This work of supporting day camps for patients suffering with tuberculosis is planned to carry out the decision reached at the International Red Cross Conference in London in 1907, when it was unanimously agreed that all Red Cross societies should cooperate in the anti-tuberculosis campaign. So far as is possible, the direction of all camps which may be established will be left in the hands of those already familiar with the work, while the Red Cross will provide the funds for the maintenance of the camps. Interior changes will be made in the Vanderbilt Clinic at the same time so as to provide more room for the work. The additional space will make it possible to set up mechanico-therapeutic apparatus for the orthopedic department, and will also provide for a much needed en-

largement of the laboratory devoted to the teaching of clinical pathology.

To Color Soldiers' Underwear.—The War Department is preparing to test the efficiency of underwear which has been dyed a blood-orange color as a protection against tropical sunlight. Five thousand suits are being prepared in Philadelphia and will be sent to the Philippines for actual test. In the same way an orange-red hat lining is being prepared as an experiment.

Marines Threatened with Rabies.—Major G. H. Russell and ten privates of the Marine Corps, all of whom were bitten by a dog which appeared in Camp Diabolo on the Isthmus of Panama on July 21, arrived recently in New York to receive treatment. The men were ordered north by the War Department as soon as examination showed that the dog had had rabies. On arriving here they were sent to the Naval School Medical Hospital at Washington, where serum had been prepared and everything was ready for immediate treatment.

Surgery at Sea.—While in midocean the steamship *Cedric* was stopped for two hours to permit the ship's surgeon, assisted by Dr. Halsted of Johns Hopkins, to perform an operation on one of the cabin passengers. The condition of the patient necessitated an immediate operation, and for nearly three hours the steamship was held until the surgeons and nurses had finished their work and the patient had rallied.

Quinine in Italy.—The Government controls the sale of quinine in Italy and uses the profit to fight the mosquitos in the malarious districts. Last year the net profit on the sales was about $75,000 and this was employed in draining and filling in the breeding pools and improving the land in various ways. The impossibility of persuading the peasants to screen their houses or even to use the screens provided, or in any way to protect themselves, makes the elimination of the marshes the only means of combating the disease.

Draining Mosquito Pools.—The Board of Health of New York has undertaken the work of compelling the owners of property in the Flushing meadows to drain off the stagnant water pools in which thousands of mosquitos breed. There are a large number of such pools all over Long Island, and a strong wind sweeping over them often drives the mosquitos to Manhattan and the Bronx. The Board of Health announces that there is no larger number of cases of malaria now than in any other year.

Civil Service Examinations.—The New York State Civil Service Commission will hold examinations on September 5, 1908, to fill the following positions: Assistant physician to the Rome State Custodial Asylum, at a salary of $600 to $900 per annum and maintenance, and trained nurse at a salary of $420 to $600 per annum and maintenance. Applications for these positions must be filed before August 30, and blanks and full information will be forwarded upon application to the Chief Examiner of the Commission at Albany.

Infant Mortality in Chicago.—Six hundred and sixty-nine babies died during the month of July in Chicago. Probably two-thirds of these deaths could have been avoided, and most of them may be attributed to ignorance and neglect of the parents. The Department of Health is now directing the work of seventy-five physicians in the crowded districts of the city, educating mothers in the proper care of their children.

Chicago School of Civics and Philanthropy.—Sixty students have enrolled in the summer classes of this school, which is under the auspices of the Chicago Commons. Of this number, 24 are attendants in various hospitals for the insane, and are studying particularly the methods of rehabilitating the minds of their patients.

A Woman's Hospital.—In Berlin a woman's hospital has recently been opened with a staff composed exclusively of women. At present it contains nineteen beds and is open to the patients of any woman doctor. Such a hospital has existed for twenty-five years in the United States, the Tefair Hospital, in Savannah. The hospital has about fifty beds and is richly endowed.

Charitable Bequests.—The Methodist Episcopal Church Hospital of Brooklyn receives $5,000 under the will of the late Townsend Wandell, who was killed recently in a railway accident at Bologna, Italy. St. Michael's Hospital of Newark, N. J., receives a bequest of $1,000 from the estate of the late Mary O'Brien. The will of the late Dr. John Ordronaux, recently filed, contains among other bequests $6,000 to the Mary Hitchcock Memorial Hospital, $10,000 each to Dartmouth College, University of Vermont, and Trinity College, and $2,000 to Boston University.

Faculty Changes.—The Starling Medical College of Columbus, Ohio, has recently reorganized its faculty. Dr. John Dudley Dunham has been made professor of diseases of the stomach and dietetics; Dr. Yeatman Wardlow, professor of clinical gynecology; Dr. Sherman Leach, professor of operative surgery; Dr. John H. J. Upham, professor of medicine; Dr. E. G. Horton, professor of hygiene and sanitary science; Dr. E. A. Hamilton, professor of rectal diseases. Dr. Ernest Scott has been placed at the head of the pathological department.

Marriage Licenses.—During July, 2,773 marriage licenses were issued in New York, a falling off from the average. Of these 1,862 were issued in the Borough of Manhattan.

Visiting Tenement Babies.—The reports of the district nurses of the Board of Health show that up to August 1, the thirty-six nurses had visited 11,375 babies in the city. During the last week of July 2,175 "new cases" received attention. The visits are confined to babies under twelve months, of whom the Board estimates that there are 22,000 in the tenement house population of Manhattan. At the end of each trip the nurse records her findings on cards, giving the name, residence, and date of birth, and statements as to diet, health, bathing, cleanliness, and instructions given. The number of "unhealthy" babies listed is surprisingly small, and the number of deaths recorded quite few.

Teaching by Moving Pictures.—One house dealing in moving picture films has published a list of several hundred intended for use in the classroom; among them a number of pictures reproducing the course of an operation. These, of course, are intended for hospitals and medical schools. One series, representing six operations for removal of tumors, requires one-fifth of a mile of film. The characteristic gaits in various forms of nervous diseases are shown in another series, and others depict the behavior of the face and other muscles in paralysis agitans.

The Medical Society of the Missouri Valley will hold its twenty-first annual meeting on September 3 and 4, 1908, under the presidency of Dr. W. F. Milroy of Omaha, at Council Bluffs, Ia. Thirteen

States are now represented at the meetings of the society, which at its commencement embraced only two. An interesting programme has been prepared, chiefly of papers which are of interest to the general practitioner.

The National Negro Medical Association will hold its annual session in New York on August 25, 26, and 27.

Census of 1790.—The Bureau of the Census has just issued a publication compiled from the census returns made in 1790 by United States marshals acting under orders from President Washington. The population of the United States, exclusive of negro slaves, was 3,231,533; of New York City, 33,131, including 2,369 slaves.

Cremation Statistics.—The French branch of the International Society for the Propagation of Incineration has published a report which shows that cremation is most favored in America, where there are thirty-six crematories, which, in 1907, incinerated more than 4,000 bodies. Next comes Germany with fifteen crematories and 2,977 bodies incinerated, while in the Argentine Republic there were 976 incinerations. Other figures are: Switzerland, four crematories and 721 incinerations; Great Britain, thirteen crematories and 705 incinerations; France, four crematories and 451 incinerations; Italy, thirty crematories and 442 incinerations; Denmark, 77 incinerations; Sweden, 70, and Canada, 33.

Sir Thomas Stevenson, M. D., scientific analyst to the Home office, London, author of various works on forensic medicine, and past president of the Society of Medical Officers of Health, of the Society of Public Analysts, and of the Institute of Chemistry, died on July 28, aged 70 years.

Obituary Notes.—Dr. Elias J. Marsh of Paterson, N. J., died at his home on August 3, of heart disease, aged 73 years. Dr. Marsh was graduated from the College of Physicians and Surgeons, New York, in 1858, and later served in the Civil War. During the last year of the war he served on Gen. Sherman's staff and was often referred to as "the man who stopped the war," having been the bearer of Gen. Grant's order to "stop firing" while Grant and Lee were having the conference which resulted in surrender. For some years Dr. Marsh had been chief medical director of the Mutual Life Insurance Company. He was a member of the New York Academy of Medicine and had served on many local boards at various times.

Dr. George Michael Edebohls of this city died on August 8. He was born in this city in 1853, and was educated at St. John's College, Fordham. He was graduated from the College of Physicians and Surgeons, New York, in the class of 1875. He was a member of the faculty of the New York Post-Graduate Medical School and Hospital, and was consulting surgeon to St. Francis' Hospital, New York, St. John's Hospital, Yonkers, and the Nyack Hospital. Dr. Edebohls was best known for his earnest advocacy of the surgical treatment of Bright's disease by means of decapsulation of the kidney, an operation which he devised at the same time with, but independently of, the late Mr. Reginald Harrison of London.

Dr. James Francis Brown of Manchester, N. H., died on July 29, at his home, in his seventieth year. Dr. Brown received his medical education at the Dartmouth Medical College, graduating in 1864. He had continued in active practice from that time until his final illness.

Correspondence.

OBSERVATIONS OF SOME OF THE WORK OF INVESTIGATION AND TREATMENT OF CANCER AND TRYPANOSOMIASIS CARRIED ON BY GERMAN SCIENTISTS OF THE PRESENT TIME.

To the Editor of the Medical Record:

Sir:—On my way to Frankfort I stopped for two days at dear old Goettingen, which, like all other German cities and university towns of any importance, has been renovated and enlarged beyond recognition. Any department of science a student may choose to study he will find there amply represented by an efficient force of teachers; in medicine and surgery particularly I was pleased to see modern hospitals, clinics and policlinics conducted by well-known men who were able and ready to teach the aspiring medicus the principles and practice of the healing art fully as well as it is done in other and larger seats of learning. And then, the Goettingen University library, with its 535,000 volumes, accurately and very practically catalogued! To be sure, it needs no praise, it is known all over the world. The librarian, Dr. Lutz, to whom I had an introduction, a genial man and keen observer, conducted me through all the large halls and rooms stocked with precious volumes; finally we rested a while in the spacious reading-room, where I saw some American and a number of German scholars at work, among the latter Professor Epstein, now retired, who has written much in his time on gout, diabetes, and obesity. Goettingen has a charming location on sloping ground, a lot of fine houses in the upper town, lovely gardens and parks with magnificent trees within and without its walls. Its winter climate is somewhat severe and changeable, owing to the proximity of the Harz mountains; its water supply is excellent. Living there has ceased to be cheap in comparison to what it was in former times, but the prices charged for boarding and lodging are still quite reasonable.

In Frankfort I lost no time in visiting the Royal Institute for experimental therapy, conducted by the director, Professor Ehrlich, and his associate, Professor Apolant. The lower floor is used for experiments on animals, the second for bacteriological, and the third for biological work. Confining my observations to what was going on in the experimental department, I was met by Professor Apolant, who was very kind and courteous and showed me numerous white mice and rats inoculated with carcinoma or sarcoma, carrying tumors within their bodies of various sizes, sometimes larger than the whole animal, and living with them more or less uncomfortably for many months, the earlier or later exitus depending upon individual resistance, metastases, or intercurrent diseases. Inoculation of an animal is done in a simple but strictly aseptic way: a long glass tube, wider at the upper and quite narrow at the lower end, is sharply broken off at the latter, a bit of fresh tumor mass is sucked up, and—the broken end being sharp enough to pierce the skin of the mouse—the contents of the tube are blown out into the cellular tissue. For the purpose of immunizing mice against cancer or sarcoma, Apolant has found not only the serum but also the blood and the substance of organs, particularly the pulp of the spleen of tumor-mice equally efficient. Nothing definite can be said yet as to possible prophylactic or therapeutic results which the numerous and well-planned experiments may yield for the treatment of malignant growths in man.

In the basement of this building a number of small and large rabbits are under observation for trypanosomiasis artificially induced. The blood of recently infected animals fairly swarms with these wrigglers, they are exceedingly lively and destructive to the blood cells. The course of the disease appears to be rather acute in infected rabbits, and varies from that in man in so far as there is an early development of sores about the lips and face, falling of the fur in patches, followed by marked gastrointestinal disturbances, adynamia, and death. However, there is a remedy that will help the poor rabbit, as it has helped thousands of Africans afflicted with the sleeping sickness, and it will cure him promptly. A fine specimen of a large brown hare was shown to me in which the disease was permitted to progress nearly to the fatal end, when a single dose of a 10 per cent. atoxyl solution was administered hypodermically, which was sufficient to cure him quickly and permanently. All sores had healed and his general condition appeared to be quite normal when I saw the animal.

Next door to the Institute for experiments has been recently opened the James Speyer house, erected through the munificence of the late banker, James Speyer. It contains the offices of the Director, Professor Ehrlich, and will be devoted to chemical therapy. And near to this a new and rather large edifice is approaching completion; it will be devoted to the science of hygiene under the direction of Dr. George Neisser, who is already associated with the other two gentlemen.

The short distance from Frankfort to Heidelberg is easily covered in two hours, the train running through a fertile and prosperous country alongside the famous old Bergstrasse, with the graceful lines of the Odamwald back of it. Pulling up at the well-conducted and conveniently-located Victoria Hotel, I spent an entire day at the Samaritan House, a new hospital built especially for the investigation and treatment of cancer by and for Professor Czerny, with his own and his friends' money and a subscription from the State. Czerny, as vigorous and full of scientific zeal as ever, has retired from the chair of surgery and devotes himself exclusively to this special field of work, in the pursuit of which he has the support of Drs. Werner, von Eichberg, and others, and the very able help of the pathologist and chemist Dr. Zeller. Being again received with great courtesy by the director and his staff, we first made the rounds of the wards, where nearly every bed was occupied by patients suffering from malignant growths in more or less advanced stages. Most of them had undergone repeated operations and presented a sad and depressing sight. The visits having been finished, Czerny proceeded to do the operation of "fulguration" by the Arsonval high frequency current after de Keating-Hart. He had recently been down to Marseilles to observe and study the inventor's method. The patient was a middle aged man, still vigorous, who had been operated upon some months before for cancer of the side of the neck, but a number of painful nodules had recently recurred in the cellular tissue, the skin and cicatrix at the seat of operation remaining in good condition. A good sized flap having been detached and turned up, a few of the nodules were cut out and then the entire surface of the wound as well as the raw surface and edges of the flap were energetically fulgurated for about fifteen minutes with one and two-minute interruptions. The current-conductor was very closely applied and sometimes brought in intimate contact with the parts. By the end of the time the entire field looked pretty well cooked, shrunken, and dry. While the act of fulguration lasted the wound had copious sponging with salt solution and was finally dressed with dry gauze.

No great hopes may be entertained, Czerny thinks, as to fulguration being a means of destroying hiding cancer cells after a bloody radical operation and thereby making recurrence impossible. Fulguration does not go very deep, paralyzing cancer cells more than killing them, so that some of these may resume activity. Fulguration does good in some cases, but may also do harm. Small skin cancers may be directly and successfully destroyed by fulguration. From other remarks made by this distinguished surgeon I conclude that, though he will continue to urge and do early radical operation in every case—to which we all agree—he knows only too well that in the majority of cases the disease is or has become constitutional at the time of the first operation. Consider, for instance, a case like the one I saw some very good photographs of: a man of about 48 has a carcinoma removed from his face, remains well for a year or more, then receives by accident a few clean cuts on his arm quite a distance from his face, they heal by first intention and some weeks thereafter cancer nodules have grown in the cicatrices.

Under the direction of Dr. Zeller chemicals have also been used internally, atoxyl, for instance, for the amelioration or cure of cancer, but without any noteworthy results. The doctor hopes, however, to be more successful with a new chemical compound made and applied by him in a number of cases during this and part of last year. It would not be right and proper to disclose its name or nature here, but this I will say: that he injects the liquid neither into the tumor nor at its periphery, but away from it anywhere deep into the cellular tissue. Being taken up by the blood, it is expected to affect the cancer cells, specifically changing their character by inducing a sort of sclerosis of cell and nucleus which abolishes all further virulent growth.

Dr. Zeller possesses a lot of microscopical specimens which appear to show the sclerotic change very well indeed, and the Heidelberg Research Institute for Cancer will be ready to publish the history and results of its two years' work in October of this year in the *Münchener medizinische Wochenschrift*. In the meanwhile I shall try to obtain some of Dr. Zeller's remedy for use in hospital on my return home in September.

Leonard Weber, M.D.
25 West 46th Street, New York.

HEXAMETHYLENAMINE IN TYPHOID FEVER.

To the Editor of The Medical Record.

Sir—Referring to the letter of Dr. Heberden Beale in your issue of July 25, I call attention to the fact that I reported October 12, 1907, several cases of typhoid fever treated with formalin with recovery in about two and one-half weeks. Since then, finding the solution of formaldehyde in water rejected by so many stomachs, I have been using hexamethylenamine with good results. The duration of the cases is three or four days longer than it is in those cases which bear formalin well. I am glad to note, from Dr. Beale's letter, that others are employing this drug, which, in my limited experience of about half-a-dozen cases, has appeared to shorten the disease by one or two weeks; it keeps the temperature in check, about 103°; prevents diarrhea and distention; seems to prevent delirium, and keeps the patient comfortable. The use of this drug with regular, at least daily, high irrigation will, I believe, reduce the average duration of typhoid fever to two weeks. Its use must be begun early in the disease. I shall be glad if you will publish this brief statement because I do not think the profession sufficiently alive to the value of the drug.

W. G. Christian, M.D.
Gordonsville, Va.

OUR LONDON LETTER.

(From Our Special Correspondent.)

OFFICIAL SCIENTIFIC RESEARCHES—THE TWO SANITARY CONGRESSES—MEDICAL INSPECTION OF SCHOOLS—ANTHRAX TUBERCULOSIS AND MILK—HOUSE FLIES—INFANT MORTALITY—VISIT OF FRENCH PHYSICIANS—MR. T. BRYANT—OBITUARY.

London, July 24, 1908.

The following researches have been authorized in connection with the parliamentary vote in aid of scientific investigations concerning disease: 1. Further inquiry by Dr. Gordon as to microorganisms found in the throats of scarlatina patients. 2. Protracted and recurrent diphtheria by Dr. Theodore Thompson and Dr. C. J. Thomas; the bacteriological part by the Lister Institute. 3. Recurrent enteric fever by Dr. Thompson, with Dr. Hedingham of the Lister Institute. 4. Investigations by Dr. Savage on paratyphoid bacilli in man, streptococci in goats, and bacteriological measurement of pollution in milk. 5. Professor Delépine's research on 7,000 samples of milk. 6. Drs. Copeman and Nuttall's on flies as carriers of disease. 7. Drs. Farrar and Nuttall's on bacteriology of bedding, especially as to vermin. 8. A statistical inquiry into the social incidence of disease is to be begun, the first subjects being varicose veins and hernia, which will be undertaken by Dr. Basil Cook.

Further investigations are promised for this year.

In continuation of what I reported last week as to the Royal Sanitary Institute, I may notice briefly one or two of the discussions. Dr. M. Richards opened that on medical inspection in schools—a subject which has been very much to the fore ever since the act was passed. He deprecated the attempt to establish uniformity of method as at this early stage likely to check progress. Dr. Boobbyer of Nottingham objected to lessening the responsibilities of parents by the indiscriminate provision of crèches, play centers, and so on. He was supported by Dr. Utting of Liverpool, who asked what was to become of parental responsibility when children were brought into the world, vaccinated, clothed, fed, educated, and taught a trade at the public expense. Socialization was being carried to an extreme in regard to children, and parental control and consideration reduced to nothing. Dr. Manley regretted that some authorities believed in sanitation by handbills, which only served to light the fire or the father's pipe. He thought the time for school clinics would come, but not yet.

Dr. Berry wanted nurses appointed to visit parents and see that the recommendations of medical inspectors were carried out.

Dr. T. G. Lyon, in a paper on pure air for indoor workers, proposed to make employers liable for damages to health caused by bad air in factories, etc. Compensation should be extended beyond the few cases in which it was legally obtainable. Professor Kenwood

thereupon remarked that employers were not always to blame, for factory girls were very strongly prejudiced against fresh air.

The subject of cremation came up in another section and great differences of view were expressed.

The next day the congress returned to the subject of schools. Dr. Rose insisted that at least one or two cleansing baths per week should be given. Spray baths he thought most suitable, as with an installation of 50 sprays a whole class could be thoroughly washed in 25 minutes. An initial expenditure of at least £250,000 was required and the maintenance would only run to £60,000 a year. What would the advocates of parental responsibility say to this, and what would the overburdened rate-payers think of it? At the next congress I mean to propose that each child be presented with a stick of chocolate on arrival at school.

On the last day Dr. Eurich of Bradford contributed a paper on the control of anthrax. From over 600 examinations he was satisfied that dust from the soil was an important factor in disseminating the disease among men. But dust free from blood sank into insignificance compared with possibilities that lay in a blood-stained fleece. Yet the importance of blood did not seem recognized. Disinfection must be so applied as to penetrate every part of a bale and operatives should be taught to recognize the appearance of dried blood upon variously colored raw material. Dr. Coutts said there was a great deal more anthrax in man than got reported, and Dr. Eurich agreed with him.

Dr. Edwards read a paper urging the fusion of the Public Health and the Poor Law Services, and Dr. Thomas one on crèches, in which he attributed the high infantile mortality of industrial centres to artificial feeding.

A discussion on cows and tuberculosis, in which veterinary authorities took a prominent part, was initiated by Professor Penberthy, who considered it a national disgrace that meat was not subjected to inspection so as to prevent the traffic in diseased meat. If the money spent in gin and beer were given for pure milk less would be heard of physical deterioration. Not a little of the blame laid on the cow was properly the result of the improvidence and neglect of the home and of predisposed children. Mr. Brittlebank said it was calculated that 1,000,000 dairy cows in the country were tuberculous and that 2 per cent. of them gave tuberculous milk. Dr. Cameron held that every cow which reacted to tuberculin should be kept under special observation and examined once a fortnight. Mr. Steele pleaded for a tuberculin test of uniform strength. Mr. Willett insisted on a more efficient straining of milk. A resolution was passed to the effect that any contemplated legislation ought to be general and uniform and that increased powers should be given to veterinary surgeons

Another organization—the Royal Institute of Public Health—has held its annual congress. This was at Buxton, the spa so noted for rheumatism and at which great improvements have recently been made. The Duke of Devonshire is president this year and delivered an interesting address on a variety of subjects connected with the public health. Among them he expressed the opinion that the congress would tend to show that there need be no conflict between medical experts and agriculturists with regard to tuberculosis. Those in contact with the horrors of consumption, he said, thought that agriculturists were rather slow in taking advantage of their opportunities, but by spreading information and considering their position and feelings, the experts might gain their active support. He held that thorough examination should be made into the conditions in which milk was produced, but when this had been done the farmer should not be harassed any further. All those connected with agricultural pursuits recognized the necessity of a pure milk supply and were anxious to carry out suggestions.

Sir J. Crichton-Browne, who presided in the Preventive Medicine Section, occupied his address with two protests, one against the campaign going on in some quarters against overfeeding and the other against excessive devotion to athletics. He disputed the statement lately circulated than not more than half the proteids consumed were necessary. A mixed diet contributed to the success of the race. The culture of the Greeks and the courage of the Spartans were nourished on a diet into which flesh entered liberally. In every newspaper strenuous physical exercise was extolled. No doubt it conduced to immediate marked muscular development. But how many athletes reached a green old age, and how many who had undergone severe training and made records succumbed prematurely to heart troubles? He feared the breaking of records sometimes ended in breaking of hearts. Muscular energy was not the same as constitutional vigor.

These views were endorsed by Professor Oliver of Newcastle and Professor Ross of Liverpool.

The next day a discussion was opened by Dr. Gordon Hewlett on bacilli carriers. He spoke of the house fly's part in the spread of summer diarrhea and enteric diseases and said the deposit of waste products in the vicinity of houses should be strictly prohibited. Dr. Marden then read a paper by Dr. Davies and Professor Walker detailing the history of four personal carriers of typhoid who had communicated the disease to a number of people. Considering they had detected four such occurrences in one city within a few months, they argued that this might be a more common source of typhoid than hitherto supposed. Mr. Jacob of Liverpool suggested that flies were active agents in spreading phthisis, anthrax and ophthalmia, as well as diarrhea and typhoid. Of all carriers he thought flies the worst and rats the next. Professor Hay said the personal carrying of bacilli emphasized the necessity of thorough cleanliness. Sir Crichton-Browne said as many as 100,000 bacilli had been found on a single fly and referred to American researches showing the conveyance of diseases by these pests. He hoped they might be exterminated and they might have to take their grandchildren to the British Museum to show them a specimen of the extinct fly.

A paper on the smoke nuisance by Dr. Graham followed. He spoke of a firm who were saving £25,000 a year by consuming their smoke, and said this was the most curable of our national evils and could be got rid of in twelve months.

Another subject discussed was the spread of tuberculosis, on which Dr. Gregg of Belfast advocated a national scheme for testing all cattle with tuberculin. He said the kingdom might thus be freed from the disease in three years at a cost of less than £3,500,000. Dr. Brennan de Vine favored the slaughtering of all infected cattle and calculated the cost at £99,000 for the first year and a constantly decreasing amount afterwards.

This subject came on again yesterday, the concluding day, when Dr. A. M. Fraser advocated the issuing of an order under the diseases of animals act requiring compulsory notification of tuberculosis in animals and the destruction of the affected beasts, whether with or without compensation.

Mr. Sadler admitted the distribution of milk needed improvement, but he declared that tuberculosis declined with increased consumption of milk. If people would drink four times as much milk the disease would diminish in proportion.

Sir C. Cameron urged compulsory notification of the disease.

Professor Penberthy, president of the Veterinary Section, also spoke on this subject and submitted that a marked decline in tubercle bacilli in milk had occurred, and quoted the Local Government Board in support of his contention that the disease had decreased in Great Britain proportionately more rapidly than in any other country.

Dr. Marsden deprecated exaggerated statements about the disease among cattle. He himself dealt with from 200,000 to 250,000 carcases a year, and, although his district had the reputation of the severest inspection in England, they did not confiscate as unfit for food more than 200 cattle per annum.

Another allied discussion was on infantile mortality, in which Mr. Shelmandine said that 15,000 children in Liverpool had been supplied with immunized milk, their death rate falling one-half. Dr. Mackenzie attributed much mortality to the practice of taking infants into crowded public houses reeking with tobacco and alcohol. Dr. Broadbent commented on the dense ignorance of mothers as a cause of death to their offspring.

We have been celebrating the *entente cordiale* by entertaining a number of French physicians who have been over to see the exhibition and our hospitals. Most of the great hospitals have been visited by them. Old Bart's was specially honored, the new out-patient department and its training school attracting great attention. A demonstration of specimens in the museum was also appreciated. Of course, we had to wind up with a dinner, which we gave at the Hotel Cecil. About 170 sat down to the banquet, about seventy of them French, and the toasts were, as you may suppose, highly applauded.

Mr. Thomas Bryant, who was President of the Royal College of Surgeons during three successful years, Surgeon to Guy's Hospital for a long period, Sergeant Surgeon to Queen Victoria, etc., has received from the

College Council a very complimentary letter, congratulating him on the attainment of his eightieth year. You probably know his Manual of Surgery and may be aware that he was a most able and popular teacher. He now is Surgeon in Ordinary to the King, has held many high posts and received various honorary diplomas from universities and academies.

A notable character passed away on the 15th inst. in Francis Mead Corner, J.P. He took the College and Hall diplomas in 1854-5. He was a London Hospital student, where he became house surgeon. Then he became resident medical officer to the Dreadnought hospital ship. Then he was surgeon (and eventually consulting surgeon) to the Poplar Hospital and Medical Officer of Health to that district. Among other appointments he was surgeon to the Home for Asiatics and at one time on R. N. reserve and to H.M.S. Brilliant. He was well known and esteemed as a practitioner throughout the East End of London, had been President of the Hunterian Society and was made a magistrate for the County of London. He died of pneumonia, aged 75, and was buried on Monday.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

ATTITUDE OF THE LEGISLATURE TOWARD HEALTH MATTERS—SEGREGATING LEPERS—ARTESIAN WELLS—THE CHOLERA SITUATION—MANILA'S WATER SUPPLY—CLOSURE OF THE OPIUM HOSPITAL.

MANILA, P. I., June 27, 1908.

THE first Philippine legislature formally adjourned June 19. The action of this body, particularly with regard to its attitude toward sanitary work which is being carried on in the Philippines was watched with considerable interest and with certain apprehension in some quarters. It was generally understood that large reductions would be made in the amounts allowed for carrying on health and medical work. It is therefore agreeable to note that the appropriation for the Bureau of Health for the coming year was actually increased over that which has heretofore been allowed. There was, however, a desire on the part of the Assembly to abolish the Civil Hospital, which is maintained by the Government for the care of its civilian employees, but the opposition to this was not sufficiently strong to prevent the appropriation for this institution being made. The present hospital facilities are none too adequate in Manila, and if the Civil Hospital should have been discontinued, the American and foreign element would have had considerable difficulty in finding proper accommodations.

The work of segregating the lepers in the Philippine Islands, which is at the present time requiring large sums of money, received substantial recognition, the plans formulated by the Bureau of Health some years ago received informal approval, and the funds necessary to carry them out during the coming year were allowed.

In addition to the ordinary and regular appropriations for the Bureau of Health, the sum of $75,000 was allotted for the purpose of boring artesian wells throughout the archipelago. The necessity for these life-saving water supplies has now been fully recognized by the native population, and it is believed that when the number of wells for which there is already money available have been installed, a material reduction in the death rate may be expected. It will perhaps be remembered that in certain towns in Pampanga province after the introduction of artesian water the death rate dropped from 40 to 20 per thousand. There is apparently no reason why results as good as that should not be expected in many other towns of the Philippines.

The cholera situation in the province of Capiz shows some improvement during the past week. There have been since January 1 a total of 668 cases and 504 deaths reported from that province. In the province of Pangasinan the situation is not so encouraging, and it became necessary for the Insular Bureau of Health to take direct charge of the situation. For this purpose seven medical inspectors were sent to Pangasinan, and in those towns in which they are working the results are already beginning to become apparent. The infection, however, had already become so widespread that considerable time must elapse before the eradication of the disease can be reasonably expected. To add to the difficulty, many of the towns are afflicted with great swarms of flies, which are believed to be largely responsible for the spread of the disease.

In the town of Bayambang, at which place Camp Gregg, a United States Army post, is located, the soldiers of the command contracted the disease, and during the past few days two American lieutenants have been stricken. These are the first two white people who have been affected during the present outbreak. The military authorities at Camp Gregg have quarantined against the outside, and there is no reason to expect that there will be any further spread of the disease among the soldiers or officers. The total number of cases reported in Pangasinan since January 1 is 2,516, with 1,652 deaths.

The new water supply for the city of Manila, which was supposed to have become available for use July 1, 1908, is, unfortunately, not yet ready. Owing to a cloudburst which occurred in the vicinity of the dam, much of the preliminary work was washed away and with the early onset of the rainy season it is impossible to do much toward replacing it. Consequently, it is not expected now that the water from an uninhabited watershed will be ready for use until August 15.

The question of the improved water supply for the city of Manila is of the utmost importance. In view of the presence of cholera in the Philippine Islands there is a constant danger that the present shed, which is inhabited by over 10,000 persons, may become infected; and if the cholera spirilla should find their way into the city water mains, a disaster of tremendous proportions would, no doubt, be the result.

The opium hospital, which was recently started by the government at Cebu for the treatment of opium habitués, was discontinued after having been open for about a month. The patients were so refractory, and the general population was so out of sympathy with the movement, that good results could not be expected by this voluntary method. It has now been decided to permit the law to take its course by fining and imprisoning those habitués who are detected with opium or cocaine in their possession.

OUR LETTER FROM COPENHAGEN.

(From Our Special Correspondent.)

RECOVERY FROM DETACHMENT OF THE RETINA—ENZYME REACTIONS IN COW'S MILK—INFECTION IN CLOTHING OF THE TUBERCULOUS.

AT a meeting of the Swedish Medical Society Professor T. Widmark reported a case of recovery from detachment of both retinæ. The patient had for about six weeks suffered from repeated attacks of general illfeeling, fever, exophthalmus, and considerable decrease of visual power. On examination she presented moderate exophthalmus and chemosis, together with a detachment of the retina on both sides. Two years earlier the patient had been treated for polypoid degeneration of the mucous membrane of the middle turbinate, accompanied by empyema of the maxillary sinus. A repeated examination showed that she was still suffering from retronasal catarrh. She was therefore again put under treatment for this disease, and after the treatment had been carried out it was found that the exophthalmus and the detachment had entirely subsided.

Before the same society Mr. Chr. Barthel read a paper on the enzymic reactions of cow milk and their importance for the hygienic control of milk. He drew attention to the test, described by the Dane, Professor Storch, by which it is possible to detect whether a milk sample has been heated to 80° C. (pasteurized) or not, as one of the enzymes (the peroxydase) is destroyed at the mentioned temperature. Mr. Barthel had now found that an examination of one of the other normal enzymes might be used for detecting an undue amount of bacteria in the milk. To use the usual bacteriological examination methods was not feasible when a large number of samples had to be examined. But his method was very simple and took, at the utmost, three hours to carry out. If methylene blue (free from formalin) is added to a sample of milk, a decoloration sets in as a result of the action of a reducing enzyme found in the microorganisms of the milk. This decoloration is the more rapid the larger the number of microbes is. Mr. Barthel's method is as follows: To 10 c.c. milk 0.5 c.c. methylene blue solution is added. On the top of the mixture 2 c.c. paraffinum liquidum are poured in order to exclude the air. Place the test tube in a water bath of 40-45° C. and note the time necessary for decoloration. If decoloration occurs within a few minutes the milk contains certainly about 100,000,000 of microbes per c.c. and ought not to be offered for sale. Even in those cases where decoloration only sets in after an hour or so the milk is not fit for food, at least not for infants. Milk in which decoloration occurs in from one to three hours is of second quality. If longer time is required for decoloration, the milk is of good

commercial quality. Milk fresh from the cow requires ten to twelve hours for decoloration. In the following discussion Professor Medin said that he thought that the destruction of the milk enzymes had something to do with the causation of Barlow's disease, which occurred only in artificially fed children. He wished to warn against the buddeization of milk, a method of sterilization originated by the Danish engineer, Budde, in 1900. Budde adds hydrogen peroxide to the milk, thus undoubtedly securing a bactericidal effect. But the enzymes did not seem to tolerate this method of sterilization better than boiling. The only case of Barlow's disease which Professor Medin had observed in his own practice was in a child fed exclusively on "buddeized" milk. Furthermore, of a series of babies fed on "buddeized" milk in the Infants' Hospital of Copenhagen, not fewer than six or eight had Barlow's disease, but recovered in a fortnight, when they were given raw milk. As to the real cause of Barlow's disease, it could not be the destruction of the enzymes alone, as during the years 1886-1896 not a single case of the disease was observed in the Children's Hospital of Stockholm, notwithstanding the fact that at that time nearly all the babies were fed exclusively on boiled milk. Dr. E. Landergren drew attention to the fact that Barlow's disease had only been observed during the last ten years or so. In this period nearly all the milk on the market had been centrifuged and thus separated from the impurities and the leucocytes contained. In this way the milk was deprived of not only the greater part of its enzymes but also of a very important substance, viz., the lecithin, so that the boiled milk now contained far less lecithin than in former days. Perhaps this might contribute to the explanation of those disturbances in the nutrition which were nowadays observed in infants exclusively fed on boiled milk.

In the Pathological Institute of Upsala, Dr. Ragnar Friberger has carried out some investigations in order to solve the question in what degree the clothes of persons suffering from pulmonary tuberculosis represent a danger to his surroundings. The result has been the very gratifying knowledge that those patients who follow the usual hygienic prescriptions concerning expectoration do not seem to infect their clothes, while of course the clothes of those patients who either from personal habits or on account of the disease itself show a pronounced want of cleanliness represent a real danger to the community.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 30, 1908.

Osteosarcoma of the Knee-Joint.—Edville Gerhardt Abbott and Dr. Thomas Jayne Burrange deal with a single variety of osteosarcoma, involving a single anatomica, structure, namely, the knee-joint, and give the results of radical operative measures in a series of fifteen cases Central sarcoma of the knee-joint closely resembles tuberculous arthritis, and the only reliable guide in discriminating between these two conditions is careful, well-directed treatment. Under fixation, traction and protection the symptoms of tuberculosis in a short time subside, while under the same treatment the symptoms of sarcoma continue to increase in severity. From their experience they conclude that a radical measure, such as an amputation, for the central variety of sarcoma of the knee-joint is advised for the following reasons: 1. Early and high amputation gives the largest percentage of recoveries without recurrence. 2. Treatment by the use of toxins, which seems to be a useful adjunct, but alone, according to present statistics, gives only 15 per cent. of cures in all varieties, cannot be entirely depended upon. 3. Immediate death following operation seldom occurs if the previous condition of the patient is fair. 4. Resection is of doubtful benefit, and, in cases where there is so much at stake, should not be attempted.

The Abuse of Alcohol in the Treatment of Children's Disease.—Charles W. Townsend believes that a halt should be called in the indiscriminate use of alcohol if we are to believe that it acts as a narcotic and depressant. The point he makes in his paper is that certain partially psychotherapeutic actions of alcohol, which may have an immediately good effect in adults, are largely absent in infants and children. Most adults have a firm belief in the stimulating action of alcohol; but this is absent in infants and children. Alcohol in the adult may make him forget his worries for the time being. Children, on the contrary, live in the present, and, if they are comfortable, do not fret about past sufferings, nor do they anticipate troubles to come. To many adults alcohol is pleasing to the taste, while alcoholic drinks are generally distasteful to children. In many adults the use of alcohol has become a habit; in children this is rare. The most important factors that make towards the recovery of the infant in diarrheal diseases are, first, a cleansed and unirritated gastrointestinal tract, and, secondly, a bland and unirritating food that can be assimilated. The use of alcohol sometimes makes the difference between a quiet and an irritated stomach. He is convinced that children with acute lobar pneumonia would do far better with no alcohol at all, and his observations in a large number of cases of this disease would bear out the theory that the action of the alcohol in any considerable amount is a depressant.

New York Medical Journal, August 1, 1908.

A Method for Preventing Infection from the Skin During Surgical Operations.—J. Shelton Horseley says that it is the practice of many surgeons to use but one knife for incising the skin, and then to lay this knife aside and complete the operation with other instruments. But it must be recognized that if the knife is infected the edges of the incised skin are also infected. In order to obviate this he has adopted the following procedure: After making the incision in the skin and subcutaneous tissue, the knife is laid aside and not used further. Then a towel, folded in the middle so as to give a double thickness, is tucked about the edges of the skin and held in position by small tenacula. It is important that the towel should be well folded over the skin edges. Small safety pins may be used instead of tenacula.

Syphilis Communicated by Assault and Battery.—Harry G. Watson is sure that the number of cases of syphilis of nonvenereal origin would be much larger if all cases were recognized and reported. Most cases of extragenital syphilis are caused by kissing, or, as in the two cases he reports, by assault and battery. This method of producing syphilis by assault and battery is of special interest to the general practitioner, who may be called upon to treat wounds received in a fight. He should bear in mind that such wounds are avenues of infection from syphilis, and at the time he should inquire about the general condition and appearance of the other party. Both of the cases he reports were infected from mucous patches, being bitten by their antagonist in assault and battery.

The Solvent Action of the Sulphocyanates Upon the Lime and Magnesium Deposits in the System.—William Bentley and Bernard R. LeRoy noticed that when the saliva was normal the basic salt was one of potassium and ammonium sulphocyanates in small and about equal amounts, but that in all cases of departure from the line of health there were deposits of more or less of the lime salts in and around the teeth. This condition could, in a measure, be remedied by the administered medicinal dose of sodium sulphocyanate; this fact led him to use it in cases of arteriosclerosis in small doses, giving prompt and rapid relief to the patient, and in time producing an improved condition which he attributed to the direct action of the sulphocyanate upon the deposited salts of lime. This led to experiments in the laboratory and an exhaustive study of the question of the solvency of lime and magnesium calculi. They find that in arteriosclerosis, or in fact in all cases where there is a high blood-pressure, sodium sulphocyanate acted as by a miracle. From arteriosclerosis to renal calculi is not a far jump. The inhabitants in their section of the country suffer very much from calcareous deposits, and renal calculi are common. The analysis of one renal calculus showed it to be composed of calcium carbonate, 60 per cent.; calcium phosphate, 25 per cent., and magnesium, 15 per cent., and free from other contamination. It was with a piece of this stone that they commenced a study of the solvent action of the sulphocyanates. As a result of their studies they announce that they had in this drug a remedy which will not only slowly dissolve the already formed stone, but will prevent the formation of the calculi, or other deposits, in the system when the sulphocyanates are present in sufficient quantities. They advised against giving the sulphocyanates for any length of time without carefully watching the patient and making repeated measurements of the blood-pressure. Large doses of the drug are not called for.

Journal of the American Medical Association, August 1, 1908.

Otosclerosis.—W. S. Bryant describes the pathology, treatment, etc., of middle-ear sclerosis or atrophic middle-ear catarrh. There has been considerable confusion in regard to the disorder, but in reality the condition is a very simple one and includes not only the "dry catarrhal" but also the suppurative process. Its symptomatic importance varies with its location, the most harmful being in the neighborhood of the foot-plate of the stapes, while it is most readily diagnosticated when the pathologic process is in plain

sight in the drum membrane. It begins as a circulatory disturbance in the mucosa and is irregular in course in its incipiency. There may be initial anemia or hyperemia with fibrosis: contraction of the vessels causes anemia and this causes sclerosis. The mucosa is first affected, next the submucous or periosteal layer, where the changes are the same, except that the deposits of lime salts is greater and takes the form of exostoses. The etiology is varied; the most important cause is circulatory changes following reduced patency of the Eustachian tube. In most cases the diagnosis is made readily by inspection of the drum membrane. Any changes in it, other than those due to acute inflammation or loss of continuity, indicate sclerosis. In the insidious form with normal drum membrane, the diagnosis is made by the functional tests which indicate impairment of hearing mechanism not accounted for except by reduced stapes mobility. Treatment is directed to the correction of the systemic causes of the disturbance of the blood supply by general hygiene, tonics, rest and relief of nervous disturbances; to putting the nasopharynx into as perfect order as possible; to any local tympanic or tubal causes, and to stimulation of normal nutrition and absorption of abnormal tissue. The restoration of function to the various parts of the auditory apparatus must also be sought by massage, inflation, etc., which are useful, if employed with caution, to restore normal mobility to the parts. Without treatment the tendency is to irregularly increasing loss of hearing. The prognosis with treatment is favorable inversely with the advance and importance of the location of the sclerotic process. It is worst when the foot-plate of the stapes is involved and best when the drum membrane is chiefly affected. It is good for arrest of the process and for improvement except in the very advanced cases. In Bryant's experience, 90 per cent. of the patients in advanced stages have improved, and 100 per cent. in less advanced stages.

Aneurysm of the Heart.—J. B. McElroy gives a detailed history of a case of aneurysm of the cardiac wall, with autopsy. He concludes from his study of the literature and his observation in this case, that the most frequent cause is probably myocardial fibrosis resulting from interference with the circulation in the coronary arteries, which were sclerotic and had their orifices contracted in his patient. This, he says, also explains the most frequent seat of the aneurysm, which is in the apical third of the left ventricle and most frequently on the anterior surface. The death of his patient was due to cardiac insufficiency from myocarditis. There was also, in his case, very extensive mediastinopericarditis, clearly recent in all parts except over the aneurysm, indicating its secondary character. The aneurysm was five inches in lateral width and three in depth and its communication with the left ventrical was marked by a well defined fibrous ring, two inches in diameter. The diagnosis was made ante mortem.

Chronic Pancreatitis.—J. B. Deaver says the most frequent form is the interlobular, and that it is this with which we have to deal in the pancreatitis complicating disease of the biliary passages. The interacinar form is due to systemic conditions not yet understood, and is correspondingly less amenable to direct or local attack. The most frequent cause is doubtless some obstruction to the free discharge of the pancreatic secretion, accompanied or not with an ascending infection. Either factor alone is enough to produce it. Many other causes of chronic pancreatitis have been claimed, cardiorenal disease, tuberculosis, syphilis, etc., and Deaver thinks that microscopic examination would reveal many cases of beginning change in normal appearing organs. The local symptoms are not very significant and may be practically absent; the examination of the feces is sometimes inconclusive and demands skill not always easy to command. The symptoms depending on the derangements of metabolism, due to interference with the internal secretion of the pancreas, are most distinctive. Diabetes is often too late a symptom to be of practical value, but the Cammidge reaction is a fairly constant sign of pancreatic disease. Medical treatment is generally futile, but by surgery we can in many cases remove the underlying cause, overcome the infection, and bring about complete recovery. When secondary to gallstone disease, removal of the calculi and free drainage will, in most cases, lead to a complete subsidence of pancreatic symptoms. When the gallducts are found clear, and the causal infection has subsided, drainage of the organ by way of the biliary passages nevertheless exerts a remarkable curative effect on the lesion, especially when the diagnosis and operation are made early, before the so-called catarrhal pancreatitis has really become a chronic interstitial interacinar lesion. Moderate anemia and glycosuria are not contraindications, as both are often greatly benefited when normal metabolism is restored.

The Respiratory Murmur.—H. D. Arnold criticises the modern teachings as to physical signs in the text-books, as failing to discriminate between unfounded theories and established facts and ignoring the physical laws on which their explanation should be based. There are, it is true, many points that we cannot thus solve at present, but we can be more truly scientific and less traditional in our ideas. To illustrate his views, he takes up the subject of the respiratory murmur, in regard to which there are contradictory opinions as to the reason why there should be two types of breathing sounds, a question that can be solved by physical experiments more easily than physiologists can investigate the digestive processes. The respiratory murmur with its modifications, he shows, is rationably explainable according to the laws of physics by recognizing it as originating at two points, the glottis and the point where the minute bronchus opens into the air sac. From these its transmission depends on the structures and passages through which the vibrations are conducted, and with a knowledge of the physical laws of sound conduction and of the structural and gross anatomy, one obtains an understanding of the complex combinations of sounds in health and readily translates the variations that come with disease into terms of changes in the texture of the lung tissue. This is the real aim of auscultation of the respiratory murmur—to learn the texture of the lung tissue. Arnold gives his explanation in detail of the physical mechanism of the different changes in the respiratory sounds, and while he does not claim that it is necessarily correct, as it has not been experimentally demonstrated to be so, it is consistent with the laws of physics and offers an intelligent basis from which to carry out further investigations which shall confirm or disprove it.

Remissions in Pernicious Anemia.—W. L. Bierring reports three cases of pernicious anemia with remissions, with tabulated blood-counts. In one case the improvement followed the removal of the patient from the county farm to the hospital, where the better hygienic and dietary conditions were undoubtedly a strong factor. In several cases observed, out of a total of twenty-five in the last two and a half years, in which fermentative changes in the intestines were a prominent symptom, high colonic irrigations with physiologic salt solution seemed to be connected with remissions or improvement. Though the blood count shows a marked improvement in the remissions, there are still abnormal features indicating that a disturbance in hematogenic function still exists. At best a remission is but a partial cure, and reserve in prognosis and caution in interpreting apparent therapeutic results are always advisable. Bierring considers that the view that the disease is an expression of a toxemia—probably enterogenic in origin—is borne out by clinical studies and experimental observations, so that care of the digestive tract is a special factor in all cases. The recent work of Herter attributing etiologic significance to specific fermentations is very suggestive, and it will be of interest to learn further of his series of cases in which the treatment consisted in the removal of the *Bacillus aërogenes capsulatus* from the intestine by colonic irrigation.

Pellagra.—R. H. Bellamy finds from inquiries among farmers that decomposed corn, picked before it has matured, is considered a cause of disease in animals (except swine) and in man, and in his section some farmers will not eat corn meal or grits away from home for fear of its being made of such damaged corn. He reports ten cases of pellagra occurring in his practice, and says he has knowledge of half a dozen more in his neighborhood. There is little doubt, he says, that the disease has occurred there for many years, as a careful inquiry among physicians brings to light many unrecognized cases. Three of the cases reported were of the chronic type, one died; seven were acute, all fatal, treatment failing. Bellamy has never seen a patient recover from the acute attack, though the more chronic form averages five years' duration and may last much longer.

The Lancet, July 25, 1908.

Intermittent Claudication, or Intermittent Limping, and Obliterative Arteritis, with Illustrative Cases.—Byrom Bramwell says that the group of symptoms included under the term intermittent claudication is due to a temporary ischemia of the affected parts, and the essential clinical characteristics of the condition are absence of symptoms when the parts are at rest, the development of symptoms after exertion, the disappearance of symptoms after rest, and, in most cases, the absence of pulsation in the pedal arteries. In most cases three factors seem to take part in the production of the ischemia, which is the fundamental cause of the condition, viz. vascular obstruction, vasomotor spasm, and increased demand upon the circulation of the part which muscular activity entails. The objects of treatment are to remove the arterial condition on which the defective blood supply depends, to keep

the patient at rest and so prevent the temporary ischemia which is the immediate cause of the symptoms, to prevent vasomotor spasm, and to relieve symptoms.

A Case of Successful Removal of a Stone Weighing Two Pounds.—Owen Richards reports this case because, so far as he knew, the stone was the second largest that has ever been successfully removed, and because an account of the method employed may be of use to some surgeon who meets with a hard stone too big for removal by any of the usual ways. The stone was too large and too hard for lithotrity, and the crushing forceps failed to get a grip through a perineal incision. He cut away the lower part of the stone with an osteotome and mallet through the perineal incision while an assistant made downward pressure through the adominal wall. The stone was hard and had to be chiseled away in blocks small enough to pass through the opening. As this soon ceased to be either easy or safe, a vertical incision was made above the pubes, the peritoneum stripped upwards as far as it would easily go, and the bladder was incised vertically. The outer layer of the stone where it presented was chipped away in blocks, and the softer inner mass was cut out in the same way, till the stone became more or less hollowed. It was then possible to introduce one blade of the forceps into the cavity, and the other between the shell and the bladder wall, and thus to break away some of the stone. After a time the stone as a whole collapsed, and then it was easy to bring pieces of it underneath the wound and crack them with osteotome and forceps. The entire stone must have weighed thirty-two ounces.

British Medical Journal, July 25, 1908.

The Action of Chloroform Administered by Different Channels.—D. Noel Paton and Dorothy E. Lindsay attempt to throw light upon the etiology of late poisoning, a well recognized danger in the administration of chloroform as an anesthetic, by a study of the changes produced in the protein metabolism of the body, with more special reference to the interference with the hepatic metabolism. Such an interference is indicated by disturbances in the distribution of the waste nitrogen excreted in the urine, and chiefly by a decreased conversion of ammonia into urea. Hence the proportions of these two constituents have been more specially studied. Chloroform by inhalation seemed to indicate a stimulation of hepatic metabolism rather than a depression. Protein was present in the urine in appreciable amount in only one experiment. Apparently in the dog (dogs were used throughout the investigation) the disturbances in the hepatic metabolism produced by the inhalation of chloroform are very trifling, and the kidneys are little affected. Chloroform in oil was administered by the stomach in two instances with a distinct increase in the total nitrogen excreted; in both there was a distinct fall in the nitrogen in urea, a rise in the nitrogen in ammonia and in uric acid, with no marked change in the proportion of nitrogen in creatinin. Hypodermically there was no marked rise in the total nitrogen excretion noted. The difference between the effects of the administration of chloroform by inhalation on the one hand, and by the stomach or hypodermically on the other, is not due to difference in dose, but to its rapid elimination after inhalation, and to its slow elimination after the latter modes of administration.

The Administration of Ether by the Open Method.—G. H. Colt had made an inhaler so arranged as to allow inspiration through the inhaler, but to direct the expiration into the air without passing back through the inhaler. There seems to be no doubt that there is, on the whole, less cyanosis, less secretion of mucus, and less oozing of the tissue by this method, but the anesthesia almost always tends to become light. Perhaps this can be obviated by using an inhaler which presents a greater evaporating surface for the ether. At no time, however, is the oozing of blood less than with anesthesia maintained with chloroform. The administration of ether by the open method seems to have its uses in a small number of cases, chiefly in very anemic patients, for short operations, and in those who readily become cyanosed.

Rectal Drainage in Cases of Pelvic Abscess Due to Appendicitis.—Bilton Pollard says that in dealing with a well localized appendix abscess in any situation it is unwise to do more than is absolutely necessary for the efficient evacuation and drainage of the abscess. The appendix should not be removed at the time the abscess is drained. Holding this view, he is very averse from removal of the appendix in the original operation for pelvic abscess when this is done through the abdominal incision; and so he is not deterred from using the rectal route on account of the impossibility of removing the appendix through it. Surgeons would be wise in using the vaginal or rectal route in females and the rectal route in males for the evacuation of large appendix abscesses which are apparently confined to the pelvic cavity.

A Case of Aphasia During Whooping-Cough.—J. S. Sewell reports the case of a boy, six years old, who had a severe attack of whooping cough with commencing bronchopneumonia. He became unconscious three days after admission to the hospital, and remained so for three weeks. The child was unable during this time to utter a word. There was also paresis of the right upper extremity. The complete aphasia continued for another fortnight (five weeks in all), when he began to make inarticulate noises and to say a few simple words. The aphasia and paresis disappeared. This seemed to be due to a hemorrhage in the neighborhood of Broca's convolution and the arm area, occurring during one of the paroxysms of coughing.

Berliner klinische Wochenschrift, July 20, 1908.

Gangrene of the Skin in Scarlet Fever.—Heubner reports a case of scarlet fever which was followed by a severe adenitis and arthritis. The latter was complicated by a remarkable eruption appearing on the skin overlying the affected joints. This eruption quickly progressed and was soon transformed into an ugly dark-colored raised spot of gangrene. No parasites of any type could be found that would account for the eruption. The lesion continued for about three weeks and gave place to a granulating wound which gradually closed up. The case is interesting, being almost unique, a picture of gangrene following scarlet fever in a syphilitic child being given in Pfaundler-Schlossmann's Handbook of Children's Diseases. The author's case was probably caused by vasomotor disturbances in the skin and not by a bacterial infection. Embolic causation of the lesion could not be considered.

Antitryptic Power of Blood-serum in Cancer.—Brieger and Trebing have continued their investigations in this field and have examined fifty-five cases of cancer with reference to the inhibitive action of the blood-serum upon tryptic digestion. In the great majority of cases the inhibitive phenomenon was greatly increased. Several patients with suspected malignant disease showed the same phenomenon, and its existence in the case of most sera obtained from patients suffering from chronic diseases proved that it accompanies cachexia due to any long continued drain upon the organism. The test may be of use in differential diagnosis of cancer, the cachexia in that disease being expressed by the increase in the antitryptic power of the serum early in the course of the affection. The administration of pancreatin to the patients suffering from cancer led to a remarkable fall in the antitryptic power, the cause of this not being apparent as yet.

Deutsche medizinische Wochenschrift, July 16, 1908.

Injuries Caused by Electricity and Lightning.—Pfahl has examined a number of cases of electric shock and of injury by lightning, following the condition of the patients for long periods of time. In every case loss of consciousness for longer or shorter period was the immediate consequence of the accident. Organic lesions could be demonstrated in every case with one exception. Quite frequent were burns of various degrees of severity; several patients showed scars on the top of the skull and on the soles of the feet, sites which were quite characteristic of injury from lightning; other patients gave symptoms and signs of neuritis; a number showed lesion of the eye grounds, consisting of hemorrhages and partial separation of the retina. The majority of the patients showed nervous or hysterical phenomena in consequence of the accidents. The author urges than an examination of the eyes be made as soon as possible in all accidents involving injury by electric current so that the organic lesions caused may not be overlooked with regard to any future medical or judicial questions arising from the occurrence.

Marmorek's Serum.—Glaessner says that this serum has proved completely harmless with proper dosage in all cases he has observed. A few patients were so improved by the administration of the serum in the absence of any other treatment that a certain curative effect of the serum cannot be denied. Its use has also hastened the good effect of other methods of treatment when combined with them. Several cases proved to be refractive to the influence of the serum. Kohler, on the other hand, writing in the same weekly, has seen no encouraging results after using the serum in sixty cases of tuberculosis. While some patients were improved, this result was so irregular that its dependence upon the serum could not be postulated.

Trypsin and Amylopsin in Cancer and Tuberculosis. Pinkuss says that the subcutaneous injection of these pancreatic ferments has proved to be quite harmless in the many instances in which he has used them. On the other hand, he has never observed any improvement in patients suffering from malignant disease and treated by these ferments. Incidentally, he used the ferments in two cases of extensive tuberculous disease of the neck, and attained surprisingly favorable results. The tuberculous lesions were promptly stopped in their progress and great improvement in the local and general condition of the patients followed.

Book Reviews.

Medical Lectures and Aphorisms. By Samuel Gee, M.D., Fellow of the Royal College of Physicians, Honorary Physician to H. R. H. The Prince of Wales, and consulting Physician to St. Bartholomew's Hospital. London: Henry Frowde, and Hodder and Stoughton, 1908.

The present volume is by a veteran physician, observer, and writer, and is an interesting and valuable addition to our present books on Practice. The lectures, which are eminently readable, are on the following subjects: The history of a case of cerebral hemorrhage; the meaning of the words coma and apoplexy; large heads in children; aphasia; the meaning of the word delirium; nervous atrophy; spinal myalgia; the causes and forms of bronchitis; the nature of pulmonary emphysema; the nature of asthma; enlarged spleen in children; tuberculous peritonitis; the signs of acute peritoneal diseases; sects in medicine (dogmatic, methodic, homeopathic, pharmacological, empirical, and expectant). These lectures are followed by some sixty pages of Aphorisms, collected by Dr. Thomas J. Horder; our limited space prevents the giving of extracts, much as we are tempted to do so. In an appendix are two historical papers on the conflict of medicine with smallpox, and Abraham Cowley and his Philosophical College. The volume is small but scholarly, and cannot fail to stimulate thought; it is inviting in appearance, improves on acquaintance, and is laid down with regret, only to be taken up again for further enjoyment.

Rotunda Midwifery for Nurses and Midwives. By G. T. Wrench, M.D., Late Assistant Master Rotunda Hospital. With Introduction by The Master of the Rotunda Hospital. London: Henry Frowde, and Hodder and Stoughton, 1908.

As stated in the title, this book is for midwives and nurses; and after a very careful perusal of its pages, we can say that it admirably fulfils its purpose. Most of the books intended for nurses contain much that can never legitimately enter into the province of a nurse's work. This little volume gives all the obstetrical knowledge that they actually need, and then it stops. Again and again in the conditions beyond the nurses' powers and knowledge, the author gives as the method of treatment the advice to "send for the physician." Technical terms are carefully explained as they occur, and numerous illustrations and diagrams make clear the instruction contained in the text. The Rotunda has long enjoyed a most enviable reputation, and this little book by the late Assistant Master is worthy of the source from which it emanates.

Detection of the Common Food Adulterants. By Edwin M. Bruce, Instructor in Chemistry Indiana State Normal School. New York: D. Van Nostrand Company, 1907.

One of the results of the recent agitation of the pure food question has been to awaken the public to the fact that a large amount of our food is or was adulterated. This little volume gives a few simple qualitative tests for all the common food adulterants. It will be useful in the school, and in some cases also in the home.

Personal Hygiene in Tropical and Semitropical Countries. A popular manual, written for the use of foreigners residing in the Philippines, Cuba, and other portions of the tropics. By Isaac Williams Brewer, M.D., Member of the American Society of Tropical Medicine. Philadelphia: F. A. Davis Company, 1908.

This is a small book, slight and sketchy in character, and discussing in a superficial kind of manner almost everything appertaining to hygiene that a dweller in the Tropics is likely to be interested in. There is some sound advice in the volume, and it will doubtless be of service to any one going to the Tropics for the first time.

Lehrbuch der Specifischen Diagnostik und Therapie der Tuberculose. Für Aerzte und Studierende. Von Dr. Bandelier, Dirigierendem Artze der Lungenheilstatte Cottlens, und Dr. Roepke, Dirigierendem Arzte der Eisenbahnheilstätte Melsungen. Mit 18 Temperaturkurven auf 5 lithographischen Tafeln. Würzburg; A Stuber's Verlag (Curt Kabitzsch), 1908.

The growing popularity of the tuberculin treatment is attested by the appearance of this monograph devoted solely to the diagnosis and treatment of tuberculosis by means of this remedy. The first part of the book, the diagnosis by means of tuberculin, considers the choice of the preparation, the dilutions, the technique of injections, the dosage, the reaction, the indications and the contraindications for the use of the remedy with this purpose. The conclusion of the authors is that diagnosis by means of tuberculin aids both prophylaxis and treatment of the disease, and ought to be used both in sanatorial and private practice.

The part of the book treating of the specific therapy by means of tuberculin gives evidence of our changed views in the subject, from the first unbounded enthusiasm, when large doses were indiscriminately used, to the present time when the effect of infinitesimal doses is carefully watched, so that no harmful reaction may take place. The authors are painstaking in the minuteness of the directions given for the use of the remedy, the various preparations of which are described and critically considered. In testimony of the success of the treatment in selected cases they add a number of temperature charts, showing the progress and the permanency of the cures obtained. The book will prove very valuable to all physicians using tuberculin preparations for diagnostic or therapeutic purposes.

Kosmetik. Ein Leitfaden für practische Arzte. Von Dr. Edmund Saalfeld in Berlin. Mit 14 in den Text gedruckten Figuren. Berlin: Verlag von Julius Springer, 1908.

Dr. Saalfeld calls attention to the fact that the legitimate medical field of cosmetics has been in the past monopolized for the most part by charlatans and advertising "specialists." His book in protest of this condition of affairs, is an attempt to teach the general practitioner the therapy of various facial blemishes, disturbances of sweat secretion, diseases of the hair and nails, etc. It is a handy little volume of some one hundred pages and covers a subject which is but badly represented in medical literature of the English language.

Die Lehre von der Intubation, von Prof. Dr. J. von Bókay, Direktor des Stefanie Kinderspital zu Budapest. Mit 113 Abbildungen und 2 Tabellen in Text. Leipzig: Verlag von F. C. W. Vogel, 1908.

In this handsomely printed and well-illustrated monograph, the author traces the development of laryngeal tubage from the initial attempts of Desault in 1803 down to and through the era opened by the epoch-making work of O'Dwyer to whom he renders due praise. He considers incidentally many of the questions which have been discussed in connection with intubation such as its recent modifications, effect of trauma in inserting and removing the tube, the value of intubation in stenosis from causes other than diphtheria, tampon tubes, peroral intubation, etc. Finally follows a bibliography which covers fully 30 large pages. The monograph is without doubt the most complete exposition of the subject which has yet appeared. In fact it is an encyclopedia of the matter and brings together in one publication the essentials of the various valuable papers of the last quarter of a century.

An Index of Treatment. By Various Authors. Edited by Robert Hutchison, M.D., F.R.C.P., Physician to the London Hospital and Assistant Physician to the Hospital for Sick Children, Great Ormond Street, and H. Stansfield Collier, F.R.C.S. Surgeon to St. Mary's Hospital; Joint Lecturer on Surgery in St. Mary's Hospital Medical School; Surgeon to the Hospital for Sick Children, Great Ormond Street. Revised to conform with American usage by Warren Coleman, M.D., Professor of Clinical Medicine and Instructor in Therapeutics in Cornell University Medical College; Assistant Visiting Physician to Bellevue Hospital. New York: William Wood and Company, 1908.

The editors of this book have arranged the subjects in alphabetical order so that it is especially adapted to ready reference. In this way the work resembles a small encyclopedia, each article being written by one who is particularly well qualified to handle it. Over seventy authors have contributed to the text, many of them world famous. Among these we note Clifford Allbutt, Byrom Bramwell, Gibson, Lane, Poynton, Schmieden, Bezly Thorne, Samuel West, and other eminent authorities. Surgical matters are dealt with more from the non-operative point of view, ignoring, as seems proper in a work of this kind, the elaborate technical operations only to be done by specialists. Obstetrics is omitted, being better fitted to treatises on that subject alone.

The work is compact and closely printed. Each author has carried out the editors' intention of giving the simplest and most efficient means of treatment now in vogue rather than mentioning each and every procedure which may be employed. As a whole the ideas expressed are conservative and such as are accepted by the most advanced clinicians as safe and effective. In such modern subjects as Bacteriotherapeutics an introduction serves to make the therapeutic methods intelligible and is properly supplied.

About fifty illustrations add to the value of the text while a supplementary index aids the searcher who may use a different nomenclature than that followed in the alphabetical arrangement. The work of the American editor has been chiefly that of adapting the English preparations to the United States Pharmacopeia where this is necessary or possible. It has greatly increased the value of the book to American practitioners.

BRITISH MEDICAL ASSOCIATION.

Seventy-sixth Annual Meeting, Held at Sheffield, July 24-31, 1908.

(Special Report to the Medical Record.)

GENERAL SESSIONS.

This meeting occupied the week. Some councilors and members of the representative meeting foregathered at the end of last week to attend to questions concerning the domestic policy of the Society. The Lord Mayor held a reception for those who arrived on Monday.

Tuesday, July 28—First Day.

On Tuesday morning there was a service in the Parish Church, where the Bishop of Sheffield addressed the members and referred to the so-called Christian Science as one of those fads which are in too much evidence nowadays and are dangerous, inasmuch as they tend to keep the doctor from the sick room. Nearly 200 members, decked out in their academical robes, marched in procession from the Cutlers' Hall to the church. Early in the afternoon a general meeting was held to install Mr. Simeon Snell as President. He is Professor of Ophthalmology at the University of Sheffield, where his active life has been passed, and is also Ophthalmic Surgeon to the Royal Infirmary. Later in the afternoon the members distributed themselves among the various garden parties provided for the occasion. In the evening the Association reassembled in the Firth Hall of the University, uniform or academic dress being general. Here colonial delegates and a number of distinguished foreign guests were introduced to the President.

Then followed the presentation of the Association's prizes. The Stewart prize was awarded to Colonel David Bruce for his researches as to the cause and prevention of Mediterranean fever. The Middlemore prize to Mr. Snell for his contributions to ophthalmology. Honory membership was conferred on the Lord Mayor, the Master Cutler and the Pro-Chancellor of the University.

President's Address.—Mr. Simeon Snell, F.R.C.S. Edin., Ophthalmic Surgeon to the Royal Infirmary, Sheffield, then delivered his address. After thanking his hearers for the great honor which he had received in being made president of the Association, he referred to the two previous meetings in Sheffield. These had not been altogether without incident. At the first meeting, in 1845, the president-elect retired the day before because he was not in accord with the medical politics of the Association. The second meeting, in 1876, was held at short notice in consequence of the abandonment of the meeting, owing to local differences, in another town which had been selected. He then spoke of the changes in Sheffield since 1845, and gave a brief history of the Medical School, now the Medical Faculty of the University. Sheffield, he said, might not inappropriately be called the cradle of the study of industrial diseases. So long ago as 1819, Sir Arnold Knight read a paper before the Medical and Surgical Society in which he called attention to the high mortality from lung diseases among grinders. Dr. Calvert Holland, in 1843, published in book form his observations on the same subject, recommending a ventilating apparatus as a preventive measure. He also investigated the other branches of labor followed in Sheffield, and showed that each had its own special health conditions and rate of mortality, but the one preeminent for its destructiveness to life was fork-grinding. Many others had studied and written upon the industrial diseases of the town. The speaker himself had confined his attention to diseases of the eye, but the field here was more extensive than might be supposed, for Sheffield, being the center of the iron and steel industry, as well as one of the largest coal-producing parts of England, afforded many opportunities for study of eye diseases and accidents in relation to occupation. These might be conveniently grouped under four heads: (1) Diseases due to occupations involving prolonged use or excessive strain of the eyes and their muscles, such as nystagmus in coal miners and in other employments; (2) those due to occupations involving the use of certain poisons, such as dinitrobenzol, met in making explosives, bisulphide of carbon, and others; (3) a consideration of the effects on the eye of occupations involving exposure to excessive light or heat or both, such as burnishers, steel-smelters, electric welders, bottle makers, etc.; (4) injuries or accidents among grinders, iron and steel workers, coal miners, etc.

Mr. Snell confined his remarks to one only of these diseases, namely, nystagmus. This disease, so frequently met with in coal miners, he had shown many years ago to be due chiefly to weariness of the levator muscles induced by the constrained position of the body and eyes which the miner was compelled to assume while engaged in "holing" and certain other forms of work in the mines. He showed that it was not dependent, as some had suggested, upon the indifferent illumination afforded by the safety lamp, for it was found in cases where abundant illumination was afforded by electric lights, and also in occupations above ground necessitating a similar constrained position with overuse of the levator muscles of the eye. One curious and serious result of nystagmus was the inability which it induced in its victims to detect the presence of firedamp. The ordinary method adopted for the detection of this dangerous gas was the reduction of the size of the oil flame of the safety lamp until the luminosity almost disappeared, the firedamp then, if present, appearing as a pale blue flame or "cap" above it. The amount of gas present could be approximately estimated by the appearance and size of this "flame cap." The men responsible for seeing that the pit was free from dangerous quantities of gas were the "deputies" or "firemen." It was their duty to visit the "workings" before the colliers went to their work, and during their working shift, to ascertain how much, if any, gas was present; and throughout their regular day's work they were constantly on the lookout for any indication of firedamp. The speaker had long believed that the apparent dancing of the safety lamp, which is a prominent symptom of miners' nystagmus, would be a hindrance to the delicate detection of the "cap" indicating the presence of gas. An official, to whom he had spoken of this probable effect of nystagmus, undertook to test one of the deputies while going through the mine, and he found the man was unable to detect any but a large amount of gas, producing a long "cap" over the lamp. Mr. Snell then undertook to test practically a number of men suffering from nystagmus, and confirmed the observation of the official, that such men could not detect low percentages of firedamp. He also photographed a safety lamp by means of a camera making 150 half-inch oscillations on either side, and in the resulting pictures the flame of the lamp was so blurred that it was easy to understand why the nystagmic observer would fail to detect a delicate blue "gas cap" above the flame.

In closing, the speaker referred briefly to the advances in medicine and surgery that had been made since the time of the previous meeting of the Association in Sheffield, in 1876, and especially to the progress in ophthalmology. The knowledge of errors of refraction and their causal relation to many nervous conditions was set forth as a notable advance, and yet, he said, it was but a few years since the scoffer was heard deriding such a relation or minimizing its importance. It was no small matter that to millions of sufferers

from recurring headaches a fuller and better understanding of the bearing of ocular conditions as a cause, and a more careful adjustment of their refraction errors of muscle balance, in competent hands, had brought comfort and relief.

Sir H. Swanzy of Dublin moved a vote of thanks to the President for the address, which he said was most interesting and instructive. Sheffield was fortunate in having Mr. Snell among her citizens. He was well known as a high authority on diseases of the eye and as regards nystagmus no one had done so much to improve their understanding of it. His address was of the highest importance and value, not only as showing how nystagmus was caused, but also, what was of more importance to the community at large, how it ought to be prevented.

Professor Fuchs of Vienna seconded the motion, which was carried with applause.

Wednesday, July 29—Second Day.

This was a very crowded day—all the sections began their sittings in the morning and were well attended. In the public health section a question of vital interest to Sheffield was discussed, viz., the smoke abatement. The Lord Mayor, the Medical Officer of Health and other citizens took part in the discussion. Gas for working and heating was dealt with. The practical result obtained in some of the great furnaces was illustrated; in some instances the time that smoke was emitted was reduced to three minutes per hour, instead of from fifteen to fifty. Another speaker condemned gas fires in small houses as a "confounded nuisance" and spoke of the detrimental effect of gas fumes. He did not oppose the abolition of smoke, but the introduction of things that were worse, and added "Let us have a little common sense as well as scientific knowledge." In another section citizens took a part, and Commander Scott, R. N., the Chief Constable, read a carefully prepared paper on the Inebriates Acts, 1879 and 1900, in which he related some of his experiences exemplifying some of the difficulties of administering these acts. The greatest of these was the reluctance of magistrates to break up the home of the inebriate—this being, in Commander Scott's opinion the rock on which the legislation split. The effects were too drastic, the results too small. Drs. Claye Shaw, Wand Cousins and J. Stewart joined in the discussion.

Address in Medicine.—Dr. James Kingston Fowler, Dean of the Medical Faculty of the London University, then delivered this address, taking as his title "Modern Medicine." He wished to protest against the too prevalent impression that the great advances in the healing art had been made by surgery alone, medicine having been more or less standing still. Surgery had but one victory to win; the triumph over sepsis laid at its feet vast territories where the knife was scarcely known, but in some of which the physician had hitherto held a feeble sway. Not so with medicine, which was required to attack separately problems of infinite difficulty presented by each disease and every organ of the body, and found no single light which illumined every dark recess of its ignorance—an ignorance which it shared in common with all the other sciences, and which in our several spheres it was the duty of each one of us to attempt to remove. He ventured to claim that, having regard to the wide field which it covered, the advance of medicine had during the last thirty years been infinitely greater in the mass than that of surgery, although, perhaps, not so readily appreciable by the public; and he expressed a confident belief that we need have no fear for the future, that it would far outstrip the past, that we were as yet but on the threshold of the knowledge which would reveal the methods of Nature in dealing with disease. Referring to bacterial therapy, the speaker said that the process followed by Nature in the cure of an infectious disease, and in conferring upon the individual immunity to it in the future, stood now to some extent revealed. The first stage in this march of Science ended with the proof that organisms were the cause of the infectious diseases. The second closed with the demonstration that by cultivating the bacteria under artificial conditions their pathogenic virulence could be greatly reduced, and that while an animal can be killed with a very small dose of the organism freshly isolated, a similar or larger dose of the attenuated virus will produce only a slight illness. The third stage was reached when it was shown that the animal thereafter was protected against repeated doses of the actively virulent culture of the organism, and that the artificial production of immunity had been attained. Up to this point there was no difference of opinion, but beyond it rival theories contended for mastery. The weight of opinion appeared to the speaker to be overwhelming in favor of the view that agents other than the leucocytes played the more important part in immunization. Some of these substances were present in the blood serum of a normal animal that had been submitted to no immunizing process; others appeared in the blood as the result of infection, whether occurring in the ordinary manner or induced in the process of artificial immunization by bacterial vaccination. The bacteriolysins were substances which dissolved microorganisms; the agglutinins caused bacteria to swell up, to lose their motility, and finally to aggregate in clumps. The opsonins were substances which did not kill the invading bacteria, but produced in them a chemical change of such a nature that they were rendered susceptible to the phagocytic power of the leucocytes. There was no room for doubt regarding the great advance which the introduction of vaccine therapy marked in the treatment of infectious diseases. Staphylococcal and many streptococcal infections were cured by this means, especially when it was possible to use a vaccine made from the patient's own strain of this microorganism. Many local infections with the colon bacillus were now curable. A theory which was eminently practical in its application, which had been explained by a study of the opsonic index, was that of autoinoculation. According to this theory, a process of autoinoculation from a focus of infection within the body might be induced by active movements of such a sort as to cause this focus to discharge itself. In a case of pulmonary tuberculosis with a lesion which was neither arrested nor quiescent, exercise beyond a certain moderate degree almost invariably caused some amount of pyrexia, either temporary or permanent, a fact which was now to be explained on the theory of autoinoculation. The speaker then referred to the system of graduated labor which had been introduced in the Frimley Sanatorium of the Bromley Hospital with excellent results. The nonfebrile patients were given work to do in the construction of a reservoir, the effort of the labor being carefully watched in each case. In 95 per cent. of these cases the opsonic index was found to be above the normal at some time during the day. The change in the physical appearance of these patients was so great that at the end of their treatment they looked more like navvies than consumptives. Such individuals, it must be remembered, were often weaklings before they were consumptives, and if their disease was merely arrested, weaklings they would have remained. Concerning the value of tuberculin treatment in pulmonary tuberculosis, Dr. Fowler said he hoped and believed that sanitarium treatment and vaccinetherapy would prove of material assistance in the warfare against the disease. He hoped, however, that there would never be a repetition of the lamentable lack of judgment, of self-control, and of those critical faculties which should characterize the members of a scientific profession which was displayed in 1890 and the following years. If to-morrow we were

in possession of an absolutely certain remedy for pulmonary tuberculosis, probably nearly two-thirds of the existing cases would be beyond the hope of cure. There was no drug known which was not limited in its effects by conditions of the body and the extent of the disease, which latter in cases of pulmonary tuberculosis was generally about three times greater than the physical signs indicate. These facts ought to give pause to those irresponsible directors of the lay press who were careless of the hopes they excited or the grief which they caused so long as they obtained sensational copy to increase the sale of their papers. Concerning the physician of the future, the speaker said that there were many who thought he would be merely an immunizer. He hoped it would be in his power, indeed, to afford immunity to the great majority of his patients, but he must continue to be in the future, as he has been in the past, preeminently a clinician. In the future, as in the past, the first and most important thing would be the diagnosis of the patient's malady. Once that had been accurately determined, the rest was comparatively easy. The one thing that could not be read up was "diagnosis"; that must be learned at the bedside. Some thought that as medicine became more and more firmly fixed upon a sure basis of science the diagnosis of disease would gradually prove an easier task. It would become more certain in competent hands, but it would never be easy. The recent increase in the number of laboratory tests available was surely leading to the disuse of the older methods of investigation, the employment of all the senses with which Nature had provided us. It must have occurred to every physician to be called to a case in which the condition of the blood and of every secretion that lent itself to examination had been carefully investigated, not once only, but several times, and yet the diagnosis was as far, if not further, off than ever; whereas, an intelligent use of the old-fashioned methods of inspection, palpation, percussion, and auscultation showed that it was literally staring one in the face. In so saying he would not be thought to undervalue the very great assistance given to diagnosis by the newer methods. He was only urging that the older should not be allowed to fall into disuse. Regarding the rights and the duties of the medical man, Dr. Fowler said we were frequently reminded that ours was a noble profession, and one which gave a continuous interest to life and to which it was a source of pride and honor to belong; but he had observed that this reminder often preceded an attempt to place upon shoulders already overburdened with unpaid labor, some further duty similarly recompensed. To this there was a limit, which had long since been reached, if not overstepped. The public was apt to take a profession, like an individual, at its own valuation, and it might be to our advantage in the future to let it be known that we regarded our services as worthy of their due reward.

Sir Wm. Whitla, who has been chosen President for next year, moved a vote of thanks to Dr. Fowler for his address, and said the association had never had a more lucid, instructive and scientific address, which sounded like a chapter from the Arabian Nights. Dr. Burgess seconded, and the motion was carried by acclamation.

In the afternoon a congregation of the University was held and the degree of D. Sc. conferred on the President and fourteen other members or visitors. The Vice-Chancellor, Sir Charles Eliot, said the University, only in existence three years, had been glad to afford the hospitality of its buildings to the association and to add to their roll bodies which coalesced to form the University; the oldest was the Medical School, founded in 1828. It was a matter of congratulation that a member of their synod, one of their professors, was President on this occasion. The recipients of the degrees were then presented by Prof. Appleton, with appropriate references to their several claims to distinction. There were several garden parties afterwards among which the visitors distributed themselves. About a hundred visited the Model Dairy at Sandygate. In the evening there was a civic reception in Weston Park, which must hold the first rank among all the social functions, which have kept up if they have not surpassed Sheffield's reputation for hospitality. Myriads of fairy lamps among the flowers, bands of music, a concert by Neapolitan singers and, later still, a display of fireworks closed this crowded day.

It should be added that some of the great steel works were opened to visitors, many giving great interest and surprise to those who went; for example, the rolling mills where sheets of steel were being prepared for making pen-nibs. A crucible shop dealing with 50 tons a day manufacturing armor for H. M. ship Collingwood, where the straightening and bending of plates under 6,000 and 3,000 tons hydraulic presses could be witnessed.

Thursday, July 30—Third Day

This also was a busy day. At 8 A. M. the breakfast of the National Temperance League was given, and a large number attended it. At 9 o'clock there was a gathering at the University to hear Professor Neisser of Breslau, who has lately returned from his three years' research work in Java. He went to study certain of our specific diseases in anthropoid apes and other animals, and he believes he has elucidated various points in connection with these diseases and methods of treatment which may be effectual. He began his work in 1905. After a time he had six medical men working with him and twelve Malay assistants. All lived in the centre of a wire enclosure in which 600 to 800 animals were kept under observation. For the first year the cost was borne by Prof. Neisser himself, but afterwards the Dutch and German governments relieved him of this expenditure. At 10 o'clock the sections again met. Later the Irish Medical Graduates' Association and the Anglo-Continental Medical Societies held their meetings. But the event of the day was the

Address in Surgery.—Professor R. J. Pye-Smith delivered this address, taking for his subject "Prophylaxis in Surgery." Vast as were the fields in operative surgery opened up by antiseptic methods, he said, it was in prophylaxis that the results of antiseptic precautions were chiefly seen and were of such far-reaching importance. The prevention of the bacterial infection of operative wounds (operative asepsis) was the glory of antiseptic surgery. But when sepsis was already present, or where the potentially-infective mucous membrane of the alimentary canal was involved in the operative area, we must trust in a greater degree to the natural resistance of the tissues, and supplement this not only by an aseptic operative technique, but also by all the means at our disposal for the specific immunization of the body. Such materials as nuclein (for inducing hyperleucocytosis), serum, normal and variously modified (for supplying antimicrobic, antitoxic, and various other chemical substances), and bacterial cultures, dead or living (for stimulating the manufacture of such substances in the blood), were on their trial. We were probably on the eve of discoveries in the practical use of vaccines which would bring both acute and chronic infections under control, and place in our hands another weapon wherewith to prevent the late and often fatal stages of both local and general infection. It might seem rather late to speak of prevention when a disease had advanced so far as to call for surgical measures, but that depended upon what it was we hoped and tried to prevent. When a patient already had a tumor we might still hope to prevent its development and fatal termination. Again, in the performance of the necessary operation in such a case, we had it in our power to prevent pain by the exhibition of an anesthetic, to prevent dangerous loss of blood by efficient hemostasis, and to

prevent bacterial infection by an aseptic technique. So, when we failed in keeping away the seeds of disease, we might still, perhaps, get at the root of the mischief, or nip it in the bud, and, if not even that, we might be able to prevent its wide spread or some of its most injurious effects.

The speaker then took up the various forms and kinds of prophylaxis, and in speaking first of legislative prophylaxis he noted as a brilliant example of the successful result that occasionally rewards legislative and administrative prophylactic action, the present banishment from this country in the dog, and consequently in man, of that terrible and uniformly fatal disease, hydrophobia. Many other countries had still to fall back on the second line of defense provided by the no less truly prophylactic vaccine obtained with such admirable patience and insight by the experimental labors of Pasteur.

In operative surgery we were especially concerned in the prevention of pain, hemorrhage, shock, sepsis, and death. The prevention of pain was of course obtained by anesthetics, but there was a wide choice of methods of inducing anesthesia. For major operations inhalation anesthesia by chloroform, ether, ethyl chloride, or nitrous oxide, or by a mixture or sequence of two or more of these, was necessary and was, when in competent hands, a reasonably safe procedure. But it had its disadvantages in the way of vomiting, the preliminary starvation, the horror which some felt of becoming unconscious, etc. An efficient substitute in certain cases was local anesthesia induced by the application of cocaine and substances with similar action, or the infiltration anesthesia of Schleich. Intraspinal injection was a method of great promise, but for the present it appeared to have anatomical limitations to the lower part of the body. In the prevention of hemorrhage a very great advance was marked by the introduction of the Spencer Wells pressure forceps, by the application of which before the division of each vessel, in the majority of operations hemorrhage may be almost entirely prevented. The use of the elastic band after elevation of the limb was also a most valuable means of preventing loss of blood in amputations and of securing a clear operative field in other cases, though the later oozing was an objection. Shock was largely prevented by anesthesia and hemostasis, but it might result from other causes, one little recognized cause being neglect to keep the patient warm before and during the operation. Celerity and gentleness in operating were factors of prime importance, and last but not least was to be noted the good effect of hope and cheer.

For the prevention of sepsis the world was indebted to Lord Lister. The exclusion of living lacteria from the field of operation was effected on the one hand by washing them away and covering them up, and on the other hand by destroying their vitality by means of heat and of chemical substances. Washing formed the general preliminary preparation; heat was then trusted to for the sterilization of instruments, gloves, cloths, swabs, dressings, and almost every article used; but for the skin and mucous membrane of the patient and for the skin of the surgeon chemical substances had to take its place, supplemented by a covering of sterile cloths or india-rubber gloves. These last formed one of the most valuable of the comparatively recent improvements in aseptic technique. Quite equal care had to be taken in the preparation of the hands before the gloves were put on as was necessary without them, but they had the double use of protecting the patient against bacteria lurking in the surgeon's skin and of protecting the surgeon's hands from contamination by pathogenic bacteria. They were thus equally valuable for operating and assisting, for dressing and examining, in septic and in aseptic cases; and the danger of septic infection from the hands if a glove was pricked or torn did not seem to be great if the glove was at once changed or the prick covered by a finger-stall. Finally, was the question of the prevention of death, the most important of all the considerations before the surgeon's mind, and to which all others were subordinate. Hemorrhage, shock, and sepsis being the three chief causes of operative mortality, it was evident that their prophylaxis was of prime importance. Carefulness and judgment were also always necessary, and we must never disregard the dangers that inevitably attended the induction of anesthesia and the performance of any cutting operation. No operation could be undertaken without risk, though in most cases the risk was happily but small. In this, as in the practice of asepsis, we aimed at perfection, well knowing that it was beyond our powers to insure its achievement.

Mr. Pye-Smith then took up the question of prophylaxis in the various surgical diseases and accidents of the eyes, nasopharynx, ears, chest, abdomen, pelvis, and extremities. In the case of appendicitis he urged prompt operation in the first attack, within twenty-four hours, or earlier. Operation at this stage was little if any more risky than an external operation, and it was preventive of further trouble. If an expectant plan were adopted in the first attack an explosion of violent symptoms might put the patient in great jeopardy, and an operation then might be too late. If the patient recovered from the first attack he would still have to submit to operation later or remain possessed of a damaged and dangerous appendix. He did not maintain that the removal of every inflamed appendix during the first twelve or twenty-four hours of its first attack was an altogether ideal method of prophylaxis against complications and recurrence; but he was convinced, from his own experience, that it was an efficient method, and the safest and best at present practicable. We might look forward to the time when such advances might have been made in the etiology as to provide a less clumsy means of preventing inflammation of the appendix than its amputation; but that time was not yet.

In concluding, the speaker said: "Prophylaxis is always full of hope. It is founded on early and correct diagnosis, together with the prognosis which is the outcome of knowledge and experience, and which enables us to prophesy because we know. But in much of our surgical work to foretell should be to forestall. We need to recognize what is ahead of our patients, to provide for the emergency, to anticipate the complication, to avoid the danger. Pessimism and despair, born of ignorance, can lead but to disaster, whilst optimism and hope must always be right, when founded on knowledge and insight. 'Your intelligence,' says Ruskin, 'should always be far in advance of your acts.' We must set before ourselves an ideal, true to Nature, but too high for immediate and habitual attainment, that so both our individual and our collective work may be more worthy of our calling, and that our art may be more hopeful and more helpful to suffering humanity. 'Not failure but low aim is crime.'"

In the afternoon there were more garden parties and further opportunities to see the great works which make Sheffield's prosperity. The annual dinner took place in the evening, with the usual supply of post-prandial oratory, and the ladies were entertained at a special performance at the theatre.

Friday, July 31—Fourth Day.

Final sectional meetings, more inspection of works, luncheons, etc. In the evening the "Popular Lecture" was delivered by Mr. Owen of St. Mary's Hospital, London, after which the President and local members gave a reception in the Cutlers' Hall.

Saturday, August 1, was devoted, as usual, to excursions, but most of the visitors had left or were leaving.

Next year's meeting is to be at Belfast, and Sir W. Whitla is the President.

SECTION OF MEDICINE.

Wednesday, July 29—First Day.

DR. WILLIAM DYSON OF SHEFFIELD, PRESIDENT, IN THE CHAIR.

Splenic Enlargements Other Than Leukemic.—Professor W. OSLER of Oxford in opening this first set discussion alluded to the obscurity of the subject owing to our imperfect knowledge of the physiology of the spleen. He then gave a clinical classification of the chronic enlargements of the spleen, dividing his subject as follows, and making comments at different points: (1) Enlargements of the spleen in disturbances of metabolism and in intestinal affections of children as seen in rickets, amyloid disease, also in a large ill-defined group in children. (2) In chronic infections, as in syphilis, malaria, kala-azar and other forms of tropical splenomegaly, in Hodgkins' disease and in tuberculosis. (3) In primary disturbances in the blood-forming organs, as in leukemia, possibly in chlorosis, certain cases of pernicious anemia and in splenomegalic polycythemia; (4) in association with cirrhosis of the liver whether syphilitic or alcoholic, in hypertrophic cirrhosis, either Hanot's or with haemachromatosis; (5) hereditary and family forms and in isolated cases as in the congenital acholuric icterus with splenomegaly, and in the family form of splenomegaly with dwarfing; (6) in new growths as in diffuse infiltrating sarcoma and the infiltrating endothelioma of Gaucher; and (7) those not hitherto correlated with any of the foregoing or any known cause, as in simple splenomegaly, in splenomegaly with anemia and in that with anemia jaundice and ascites, splenic anemia, and Banti's disease.

A remarkable feature of the last group of cases was that the condition might in some cases be cured by surgical removal of the spleen.

Professor W. BOUCHARD of Paris, speaking in French, referred to what he had previously described as the splenic souffle in the enlarged spleen. Of five cases, in three there was an associated cirrhosis of the liver and in two others a cirrhosis was probable. He had also heard it in a case of splenomegalic leukemia. In the same cases he had observed marked systolic expansion of the arteries and capillary pulsation—but no sign of aortic insufficiency. In the cirrhotic cases he had also noticed naevi and serious internal hemorrhages. He had seen distinct improvement in some of the cases follow the internal administration of calomel.

Professor W. SAUNDBY of Birmingham remarked that on looking through his case-books and excluding leukemia he had found the more frequent causes of splenic enlargement were lymphadenoma, heart disease and in association with cirrhosis of the liver. Others less frequent were malaria, tubercle, syphilis, pernicious anemia, splenomegalic polycythemia and thrombosis of the splenic vein. The cases associated with jaundice occurring in families through successive generations he would distinguish from some of the cases called splenic anemia, or Banti's disease. Many of the cases occurring in families proved fatal, but in others there was but little depreciation in general health. It was probable that congenital cholemia occurred in various degrees of intensity.

Dr. G. A. GIBSON of Edinburgh confined his remarks to splenomegalic polycythemia. He described a case then under his care in hospital of four years' standing. Free hydrochloric acid was not found after test meal. Improvement followed the application of the *x*-rays, but relapse shortly occurred. Improvement again followed *x*-ray treatment, which lasted for nearly two years, but the splenic enlargement became greater than ever and instead of 4,500,000 there were 12,000,000 red cells, 120 per cent. instead of 87 per cent. haemoglobin, 30,000 instead of 10,000 leucocytes, as before the relapse. The patient became purplish, the viscosity was twice, and the coagulability of her blood twice the normal. A portion of red bone marrow was removed surgically from the tibia and this showed on microscopic examination dilatation of the blood channels, marked diminution of the myelocytes, increase in the nucleated red cells and in the fully formed red cells, also large aggregations of small cells of uncertain nature, which might be small lymphocytes or possibly small nucleated red cells. The whole, however, pointed to changes in the bone marrow as at least a large part of the essential underlying changes in the condition.

Dr. H. D. ROLLESTON of London would have liked to limit the discussion to the cases in which the spleen alone was enlarged. Chronic splenic anemia of adults ought to be recognized as a definite clinical condition, not as a disease, but for the post-mortem the changes in the spleen were not always the same. Two types of changes might be recognized, one with marked fibrosis and endothelial proliferation, and the other (Gaucher's type) a chronic endothelioma, possibly a primary new growth, but probably not. He would distinguish Banti's disease from chronic splenic anemia; the former should be limited to terminal cirrhosis in chronic splenic anemia. In cases of syphilis the enlargement of the spleen was not necessarily syphilitic; it might be due to some other chronic infection, possibly predisposed by the syphilis. Any enlargement of the spleen in heart disease (apart from ulcerative endocarditis) was probably due to some complication, as embolism back-pressure alone was not, he thought, sufficient to cause it. Referring to operation, he thought the danger of removing the spleen in chronic splenic anemia was very great, particularly from the occurrence of secondary hemorrhage. Of the cases of enlargement of the spleen with jaundice, the congenital cases might or might not be hereditary. In the congenital cases the patients bore the condition very well, but it might ultimately become transmitted. The congenital cases showed more jaundice and less anemia—in the acquired cases the reverse was the case. In chronic splenic anemia with jaundice it had been suggested that the spleen was responsible to a haemolytic jaundice and that the red blood cells were more vulnerable and smaller than natural. The blood changes in the jaundice cases were much those of chronic splenic anemia, and it was probable that these cases ran into each other and into Hanot's cirrhosis and Banti's disease. The view of a chronic infection and a subsequent cholangitis was, he thought, more attractive than the hemolytic view.

Dr. J. GALLOWAY of London showed a specimen of a spleen from a child aged seven, with only little blood change and jaundice, but with considerable pigmentation; a drawing of a case of Hodgkins' disease with lymphadenomatous tumors in the skin and intense pruritus; a specimen showing the influence of syphilis on the splenic enlargement; there was chronic heart failure with back pressure; he had persistent anemia and great enlargement of the spleen. There were found syphilis of the heart and obliterating arteries in the spleen, whether primarily syphilitic or secondary.

Dr. ROBERT HUTCHISON of London discussed the chronic enlargement of the spleen in children—all, as a matter of fact, being of the non-leukemic sort. The commonest was the condition *pseudoleukæmia infantum*, characterized by chronic enlargement of the spleen, anemia, and a degree of leucocytosis. Two causes had been assigned, rickets and congenital syphilis; rickets might be at once excluded, and the latter might be excluded in at least half of the cases. After the age of 2 many of the cases of splenomegaly were survivals of *pseudoleukæmia infantum*. Others might be a purely splenic form of lymphadenoma; their occurrence was, however, not yet certain. Other cases occurring up to the age of 10 or 12, diagnosed at first as splenic anemia, were marked by hemorrhages, jaundice, and ascites, which was followed by death; these cases resembled very rapid cases of Banti's disease. In some of these cases there

was evidence of congenital syphilis. Many cases of splenic enlargement in children were really the reaction of lymphoid tissue to a chronic intoxication by a syphilitic or other process.

Dr. W. Hunter of Glasgow referred to three cases of splenic enlargement that he had had under observation lately.

Dr. C. H. Melland of Manchester confined himself to the consideration of a group of cases like leukemia, but with no leukocytosis, only enlargement of the spleen with myelocytes in the blood and the other blood changes of leukemia. To one group of cases the term leukanemia had been given. These should be distinguished from early cases of splenic anemia, or Banti's disease, as in them no removal of the spleen could be of use.

Dr. F. Eve of Hull argued that if operation were to be employed at all in Banti's disease it should be before the liver became cirrhotic.

Dr. W. J. Tyson of Folkestone referred to congenital syphilitic enlargement of the spleen in children and said that the splenomegaly might be the only sign of the condition, and it in the course of years disappeared so that a good prognosis might be given from the first.

Dr. T. W. M. Ouston of Sutton Bridge brought forward a case of splenomegalic polycythemia with chronic rheumatoid arthritis in which improvement followed venesection.

Professor Osler, in closing, said the splenic souffle was not often heard, because not often listened for. It was not according to his experience that the spleen was involved without the lymph glands in lymphadenoma. The two groups of cases of splenic enlargement with jaundice would probably be soon differentiated into those (1) with good health and acholuric, and (2) the fatal cases. Operative treatment was not called for in a large proportion of the cases, for they lived on comfortably for years; the two conditions, however, calling for operation were the recurring hemorrhages and the early appearance of jaundice, indicating liver implication. The points in regard to chronic splenic enlargements calling for early elucidation were (1) the family forms, (2) the cases in children, (3) the exact relationship of the group of cases of chronic splenic anemia, and the variety of polycythemic splenomegaly.

SECTION OF OBSTETRICS AND GYNECOLOGY.

Wednesday, July 29—First Day.

Mr. Richard Favell of Sheffield, President, in the Chair.

Treatment of Displacements of the Uterus.—Dr. Herman of The London Hospital opened this discussion. divided uterine displacements into two classes: (1) The rare forms: (*a*) inversion, (*b*) uterus in hernial sac; (2) the common forms: (*a*) downward, and (*b*) backward displacements. In most cases of downward displacement there was nothing wrong with the uterus itself but the lesion was due to defects in the pelvic floor and it was now agreed that in cases of flexion the curve in the uterine canal was not a disease. When the uterus was retroflexed pressure on the veins led to congestion and tenderness of the organ. There was slight descent in all women in the upright position, and this was allowed by inversion of the upper part of the vagina. In the slight cases when much pain was complained of there was usually neurasthenia, and it cannot be too thoroughly recognized that in some cases the whole of the symptoms were due to neurasthenia, but in other cases dragging pain and irritability of the bladder were complained of when there were no signs of either neurasthenia or prolapse. If cases were relieved by a pessary he would never think of operation; when an ordinary pessary was not retained he would try one of these supported by a waist belt. He considered that to keep up the uterus by a mechanical support was harmless and generally effective, but in some cases they could not be retained. Various operations were then practised by different operators, some of these, such as injection of paraffin or of irritant substance into the broad ligament, he did not approve. In cases where a pessary proved to be inadequate, if the patient was beyond the child-bearing age, he advised colporrhaphy with the subsequent use of a pessary. But permanent relief could only be obtained by combining this operation with ventrofixation, and one must unite the peritoneal surface of the uterus to the muscle of the abdominal wall; he did not approve the ventral suspension of Kelly; the operation should not be advised in child-bearing women. Vaginal hysterectomy was of no use, but he approved of complete extirpation of both uterus and vagina.

Professor Pozzi of Paris, who spoke in French, thought that the anteversion associated with dysmenorrhea was usually a congenital condition, as insisted on so strongly by Lawson Tait. In France there was a reaction against pessary treatment, which in his opinion had gone too far. If Alexander's operation was performed one must be sure that the appendages were normal and that the abdominal parietes were strong enough. Of vaginal fixation he had not much experience, his favorite operation being ventral fixation with intraabdominal shortening of the round ligaments.

Professor Bossi of Genoa, who also spoke in French, showed an intrauterine stem pessary which he used for flexion associated with dysmenorrhea.

Dr. J. Riddle Goffe of New York agreed with Dr. Herman that in many cases the symptoms were really due to neurasthenia and that the condition was one of "sore brain" rather than "sore womb." He believed that the uterus was suspended by its ligaments and instanced the lungs, liver, spleen, and intestines as other viscera suspended in a similar way; there was no organ which had so many ligaments as the uterus. He pointed out that prolapse was exceptional in cases of complete rupture of perineum and was frequent in nulliparæ, showing the little value of the pelvic floor as an agent in sustaining the uterus. He said that there was a great reaction in the United States against pessaries.

Dr. Arnold Lea of Manchester said that in many cases prolapse was associated with relaxed abdominal walls and general ptosis of viscera. Gymnastic exercises were very useful, especially those directed to strengthening the muscles of the abdominal wall; in uncomplicated cases he shortened the round ligaments. In doing ventral fixation it was most important to close the uterovesical fold to avoid danger of strangulation of intestine.

Dr. May Thorne drew attention to many cases in which retroflexion existed without symptoms. In young girls she thought that acute discoloration was sometimes due to too violent exercise, and she thought that games at school should be undertaken with great care at the menstrual periods. For these cases she advised replacement under anesthesia and the temporary wearing of a pessary.

Dr. Hellier of Leeds found that many bad cases were relieved by a pessary with external attachments, but, if they failed, he would combine ventral fixation with amputation of cervix and anterior and posterior colporraphy.

Dr. Inglis Parsons of London spoke of his well-known method of injecting a solution of quinine into the broad ligaments; he had now treated 150 cases in this way, with 90 per cent. of cures. He believed in Kelly's ventrosuspension. He allowed patients to ride and bicycle while wearing a pessary.

Dr. Hubert Roberts of London thought that ruptured perineum accelerated prolapse, and he performed colpoperineorrhapy combined with amputation of cervix where the latter was enlarged.

Dr. Archibald Donald of Manchester would confine his

remarks to mobile retroversion; in this condition there were sometimes no symptoms, and his explanation was that the symptoms when present were due to associated urethritis; on this account he considered curetting an essential part of the treatment. He did not use pessaries and thought that ventral fixation had been much overdone.

Dr. T. J. McCann of London said that in the so-called cases of neurasthenia the best results were obtained from rest, massage, and exercises. He amputated the cervix and removed a part of the vaginal vault.

Dr. Cuthbert Lockyer of London divided eight treated cases as follows: (1) Retroflexion: (*a*) mobile, no operation; (*b*) fixed, laparotomy, removal of adhesions, ventral suspension. (2) Retroflexion with tubal disease, remove diseased tubes and perform ventrosuspension. (3) Retroflexion and pregnancy, replace in knee-elbow position. (4) Retroflexion and prolapse, bad cases, amputation of cervix, anteroposterior colporrhaphy.

Dr. Helme of Manchester, in many young girls, found cellulitis of left uterosacral ligament with retroversion, and thought this was due to too violent games with neglect of bowels at school. He used Gilliam's operation extensively.

Dr. Fothergill of Manchester thought that it was futile to maintain that injury or relaxation of the pelvic outlet was a cause of prolapse, and was convinced that the condition was due to relaxation of the connective tissue, and the latter was principally that which formed a sheath to the vessels; the only effect of a ruptured perineum was to widen and straighten the path for the uterus to descend.

Dr. Johnstone of Belfast did lateral colporrhaphy.

Dr. Blair Bell of Liverpool described Gilliam's operation by the aid of diagrams; its principal feature is that the round ligament is shortened by being pulled through the sheath of the rectus and fixed to the aponeurosis.

Dr. Buist of Dundee thought that both relaxation of the pelvic floor and of the ligaments were factors in bringing about prolapse.

Dr. Herman, in closing, thought that cases of retroversion in young girls could be cured by a few days' rest in bed. He considered the risk of intestinal obstruction after ventral suspension was a very real one.

Professor Bossi of Genoa related some cases of osteomalaria which he had treated by the administration of adrenalin with good effect.

The Displacement of the Uterus in Certain Cases of Pelvic Tumor.—Dr. Cuthbert Lockyer of London read this paper. In two hundred abdominal sections the ureter was damaged four times. The most probable causes for this accident were fibroid in the broad ligament, cyst in the broad ligament, and cancer of the cervix. He narrated a case in which one ureter was divided and the kidney removed in consequence, as the patient was too bad for prolonged operation: no urine was secreted for eighteen hours; abdomen reopened; other ureter found tied; end implanted into bladder; recovery.

Thursday, July 29—Second Day.

Cesarean Section Versus Other Methods of Delivery in Contracted Pelvis.—Dr. Robert Jardine of Glasgow opened the discussion of this subject. The selection of the operation is conditioned primarily, he said, by (1) the experience of the operator; (2) the environment of the patient. An expert has a free choice of them all; others must choose whichever in the circumstances they deem most favorable to the interests of the mother. Induction of labor or craniotomy may be possible when environment puts the other operations out of the question. In good surroundings cesarean section is to be preferred, provided labor has just commenced and careless examinations have not been made. In the contrary case, if pelvic delivery were impossible and section imperative, the author would remove the uterus. In considering the possibility of pelvic delivery the best pelvimeter is the comparative size of the head. With a true conjugate of two and a half inches the author would perform section, even if the child were dead; likewise if there were great overlapping of the head or general pelvic contraction as well as flattening. Pubiotomy is usually preferable to symphyseotomy, and both are possible, though always risky to the child, when the head is relatively small, and when with an ordinary head there is no general flattening and a brim of over three inches. Both can be performed by any practitioner, and both are preferable to section, with a suitable pelvis, and when labor has been long and other attempts at delivery have been made. If there is room for the use of the necessary instruments and the child is dead, craniotomy should be performed, and is occasionally justifiable even with a living child. Induction of labor is wrong before the thirty-second week of intrauterine life; past that date, it may be performed as soon as it becomes difficult to push the head into the brim; otherwise the nearer full term the better, whatever the date. The operation is risky for the child. In a pregnancy following one in which labor has been induced and the child has not survived, waiting until full term and section should be advised.

Professor Zweifel of Leipsic described by the aid of diagrams his method of performing subcutaneous symphyseotomy, by which the operation could be done in ten minutes. He also described a method of performing cesarean section extraperitoneally, the incision in the abdominal wall being made low down, the peritoneum stripped up from uterus, and the latter opened in its lower segment. He had performed sixteen subcutaneous symphyseotomies, four extraperitoneal cesarean sections, fifty-two open symphyseotomies, one hundred and thirty ordinary cesarean sections. The results of symphyseotomy were very much better if the labor was completed by natural means, and he was convinced that permanent widening of the pelvis followed the operation.

Dr. Lloyd Roberts of Manchester thought that symphyseotomy would die out, and that cesarean section was preferable to either symphyseotomy or induction of premature labor; the fetal mortality of the latter operation he estimated at 50 per cent.

Professor Von Kroenig of Freiburg thought that there was no fundamental difference between symphyseotomy and pubiotomy, and that both were dangerous if any means had to be used to extract the head; the disadvantage of the subcutaneous method was that hematoma might form. He had performed these operations twenty-one times, and in none of the cases did any impairment of walking powers follow. He had lost four of the children. He would not perform the operation with a conjugate under 7 c.m. He got the patient up on the second day, and said, in answer to inquiries, that he did the same with his ordinary labor cases.

Dr. Hubert Roberts of London read notes of two cases in which he had performed cesarean section twice on the same patient, and he considered that it was not justifiable to sterilize the patient when performing conservative cesarean section. He preferred cesarean section to either symphyseotomy or pubiotomy.

Dr. May Thorne of London said that in India, if cesarean section were performed on natives, sterilization was not done, on account of religious and caste beliefs.

Dr. Arnold Lea of Manchester read a paper on some cases in which he had performed cesarean section for contraction of pelvic outlet; these were cases of kyphosis, and the contraction of the outlet was in the transverse diameter.

Dr. Martin of Sheffield advocated sterilization as a routine proceeding, as on the next occasion the patient might be unable to obtain expert assistance.

Dr. Buist of Dundee thought that one advantage of symphyseotomy was that it could be done safely in unfavorable situations, as in an artisan's house. He had had good results from Prochownik's diet in the later months of pregnancy.

Dr. Smith of Toledo, U. S. A., said that in America both society and religion demanded that more consideration should be paid to the life of the child than appeared to be the case in this country; by cesarean section the delivery of the child could be effected in 120 seconds, and we might always make sure of a living child, so that in the interests of the child this operation was better than symphyseotomy or induction of labor. There was no occasion to sterilize. The incision should be made high up on the uterus, and he objected to cervical cesarean section as being more likely to be followed by giving way of the scar in a subsequent pregnancy.

Dr. Purslow of Birmingham narrated a case in which he performed a cesarean section on a woman who had been many hours in labor and attempts at delivery had been made, the result being successful. He had met with a case in which attempted sterilization by excising a portion of each tube had proved unsuccessful.

Dr. Jardine, in closing, said he was not guided by measurements of pelvis, but depended entirely on the degree to which the fetal head could be pressed into the pelvis. He advised against early application of forceps and would prefer to allow the head to mold. In every case of labor in which there was sign of infection he raised the head of the bed, but did not use douching. He made the incision high up on the abdominal wall.

Treatment of Puerperal Eclampsia by the Administration of Veratrum Viride.—Professor Mangagalli of Milan read this paper. He had treated one hundred cases in ten years. He looked upon the pulse as the chief guide, and when it was full and of high tension he administered the drug in small and frequent doses. The doctor should not leave the patient during the treatment, but should administer the drug himself. In answer to questions, he said that his usual dose was one-third to one-half c.c. (5 to 8 minims) of the tincture every hour; that he had never observed vomiting or collapse, and that he began the treatment without waiting for a fit, if there were prodromal symptoms.

(To be continued.)

AMERICAN ACADEMY OF MEDICINE.

Thirty-third Annual Meeting, Held at Chicago, May 30 and June 1, 1908.

The sessions were held in the banquet room of the Lexington Hotel, and the first meeting was called to order at 10 A.M. by

Dr. Thomas D. Davis of Pittsburg, President, in the Chair.

Best Means for the Medical Profession to Take Part in the Education of the General Public in Medical Matters.—Dr. Edward Jackson of Denver, Chairman, reported that the committee recommended that the American Academy of Medicine, as a learned society, giving attention to original research work in medical sociology, should encourage this work in the direction of popular education in medical matters, provide for the placing before the public of such papers and reports read before its members as would be of value in this work. The exchange list of the *Bulletin*, the official organ of the academy, should include educational journals and popular science publications, as well as foreign or domestic medical journals and scientific transactions. The active interest of the individual Fellows of the academy in various educational movements was urged, and the continuance by the academy itself of its studies, discussions, and recommendations regarding the teaching of physiology and hygiene in the schools. It was further recommended that an early meeting be arranged for the discussion of the education of the public by the physician in active practice through his patients.

Dr. Casey A. Wood of Chicago referred to the extreme conservatism of the medical profession concerning publicity. While a certain degree of this was admitted to be desirable, he believed it the manifest duty of the physician to instruct the public upon medical matters, particularly in regard to sanitation.

Dr. Henry B. Hemenway of Evanston, Ill., pointed out the need of the public of instruction in hygiene. He cited an instance of gross ignorance upon the part of a man in public life who explained that he had been so greatly engaged in the study of law that he was entirely uninformed upon the subject of general sanitation. He urged that there should be systematic study of such topics as the relation of the milk and water supply to the various diseases. Because the general practitioner had been absorbed in the study of the cure of disease, the investigation of its origin had been overlooked. Reference was made to the work of the Health Commissioner in Chicago as an opening wedge in the instruction of the public. To attain the greatest efficiency the giving of public lectures should be entirely separated from all personal interest, and to this end he would have the lecturers paid an honorarium.

Dr. Leartus Connor said that if the doctor would educate his community he should live as he would teach.

Dr. Philip Zenner believed that the publication of unsigned but authoritative medical articles in the daily press would in time be read with as much interest as the sporting news.

Dr. Joseph K. Weaver of Norristown believed that the best medium of instruction between the medical profession and the laity was the County Medical society.

Dr. Thomas H. Shastid of Harrisburg, Ill., referred to the commendable practice by the *Youth's Companion* of the publication each week of a half-column article upon medical matters. Illustrative of the good accomplished by such public instruction was the instance of a man applying to him for removal of adenoids because of having read an article by Dr. Woods Hutchinson. He thought the farm journals particularly valuable mediums for the publication of such matters.

Dr. John H. Tressel referred to the earnest desire upon the part of farmers for instruction in hygiene.

Dr. W. L. Secor suggested cooperation with the American Society for the Advancement of Science as a practical means of public instruction upon health.

Dr. H. Iles McNeill of Newman, Ill., suggested that the County Medical societies be influenced by the American Academy through the medium of the State societies to participate practically in the education of the laity in their individual communities.

Report of the Committee on Conference with Educational Institutions on Medical Education.—Dr. Charles McIntire, Chairman, reported for the committee its opinion of the presence of a definite field of effort for the academy in the present discussion of the educational requirements of intending physicians, viz., the harmonizing of the courses in the literary and medical colleges, so that emphasis be given to the desirability (not necessity) of a broad, liberal culture precedent to the study of medicine and the shaping of the liberal culture course to include those sciences which lie at the foundation of medicine that they may not be taken again in a medical course.

Dr. Thomas H. Shastid cited an instance in which a man had matriculated in a medical school and continued his work as a teacher through two years, attending the college only during the third year. In spite of this he obtained his diploma and entered practice. For the avoidance of false representation at medical examinations photographs were regarded as of little value, since people grow "old and fat" or "old and thin." An absolutely reliable means suggested was that of the imprint of the finger tips, which could be changed only by cicatrization.

Dr. Leartus Connor suggested that since there were to-day so many more doctors than were actually needed, all possible effort should be made to improve the future

output. He would favor the withholding of a diploma until the graduate had filled a year's interneship in a hospital.

Dr. Emma B. Culbertson of Boston agreed with Dr. Connor that the requirement of the interneship experience would be a valuable measure. In the Woman's Hospital of Boston graduates from all over the country applied for interneship, and many it was said came from Johns Hopkins. All exhibited marked ignorance regarding the relief of suffering. While she felt that a great debt of gratitude was due to Dr. Osler, he was conversely responsible for the undesirable mental attitude of young practitioners as a result of his therapeutic nihilism.

Dr. L. Harrison Mettler of Chicago desired that some authority might be operative in determining the man best fitted for chairs in colleges. He felt that in the last analysis the standard of medical education resolved itself to the character and knowledge of the faculty. He thought the plan followed in Germany of having the whole university scheme under one head offered a solution of the problem. This allowed the student to continue his studies under the teacher from whom he acquired the greatest amount of knowledge. Such a system presented the advantages of an improvement among the students and a stimulation of the faculties.

Dr. Harvey of Westboro asked Dr. Connor what plan he would suggest in requiring the interneship before graduation.

Dr. Connor admitted that there were difficulties in the way, but felt that if medical faculties could be made to realize the injustice of placing inadequately trained men upon the world an effective plan could be established.

Dr. Winfield S. Hall of Chicago agreed with Dr. Mettler that the power of choice vested in German students was a valuable factor in their education. In Germany the plan of having the institutions under government control was in strong contrast to the system in the United States, where the schools are more or less competitive. A plan of value among the American schools was said to be the holding of large clinics, attendance upon which was more or less optional with the student. Naturally he would attend that which yielded him the most instruction. He believed that if the licensing board would require a year's experience in hospital work before granting permission to practise, the suggestion of Dr. Connor could be carried out.

Dr. Harvey called attention to the fact that in Massachusetts the yearly graduation from medical schools was in excess of the number of interneships, and that this plan would prevent the graduation of a sufficient number of physicians for the demand.

Dr. Hall of Chicago suggested a shortened interneship.

Dr. Connor believed that State boards of examiners would not make such requirement unless it were backed by public sentiment.

The President's Address.—Dr. Thomas D. Davis of Pittsburg considered largely the question of school hygiene, saying that there was no subject upon which the physician was so inadequately prepared to advise or upon which his opinion was so seldom sought. He regarded it of much importance that the medical man insist upon the purchase of suitable and ample grounds for school buildings. The wisdom of this idea had been shown practically in the author's own experience in Pittsburg. He referred to the fact that in the Japanese army the tents could not be pitched until the location selected had been approved by the medical attendants, and suggested the desirability of such medical supervision in school hygiene. He touched upon the matter of preliminary education of the medical practitioner, and suggested further conferences upon the subject similar to the one held at Pittsburg in the first of the year. The advisability was suggested of securing a charter for the American Academy of Medicine.

Report of the Delegate to the Second International Congress on School Hygiene.—Dr. Helen C. Putnam of Providence noted items of special interest pertaining to the eleven sections of this congress. The section on medical inspection attracted particular interest, in that England was considering and has since adopted medical inspection in the schools. Oral sepsis and the influence of inspection on the incidence of diseases were subjects receiving special attention. In the section on hygiene of the teaching profession tuberculosis was shown to be more prevalent among teachers in the United States and Canada than in any other class. The instruction on temperance carried out in the schools of the United States was the feature meeting the highest approval by foreigners. The question of coeducation was next in interest. Instruction in the physiology and hygiene of sex was looked upon as an international problem. Two sections upon abnormal children indicated tendencies to classify according to physical and mental capacities. Suggestions were made toward less "machine work" and more individual attention. In physical training emphasis was given to supplementing physical and psychical elements of formal drill with others of initiative and exhilaration through games and dancing. In the section on psychology of education, of which Sir James Crichton-Brown was president, it was noted that many children entering school undergo depression throughout the year which short holidays fail to overcome, and that 75 per cent. of the children are unable to follow the curriculum. The children who had been in kindergarten work furnish the larger number of these failures. This was attributed to insufficient knowledge and application of physiological and psychological laws of children. Out-of-School Hygiene was the title of one section. It was stated that the full report of the congress could be secured from the Royal Sanitary Institute, London.

Dr. Philip Zenner of Cincinnati referred to the benefit resulting from a course on sexual hygiene in the public schools of one of the poor sections of his city, in that an altogether different moral tone had been noted among the pupils.

Dr. Putnam, in closing, referred to the work of the American Society of Sanitary and Moral Prophylaxis, and in particular to the work done in the school gardens in which the subject of sex hygiene was approached from a biological standpoint, embracing a study of the flowers and insects. In this work the principle was taught that the object of every living being was to perfect and to reproduce itself. While attention was not especially drawn to the subject of human reproduction the plan was approved as a means of approaching indirectly the fundamental elements of life. Dr. Putnam suggested the advisability of the adoption of some such scheme in the curriculum of the public schools.

Symposium on the Place of Women in the Business World as Affecting Home Life, the Marital Relation, Health, Morality, and the Future of the Race.—As Affecting the Home Life and the Marital Relation.—Dr. A. Stewart Lobingier of Los Angeles regarded the situation as one badly complicated and the result of the complex civilization of the day. Any discussion of the subject he thought should be governed not by preconceived notions of personal preference in an ideal state of society, but by facts as they obtain to-day. There were vital reasons impelling women to earn their living outside of the home, but how far this employment interfered with their marrying and fulfilling their obligations as wives and mothers there were no reliable data to determine. There were in addition certain definite views which led some women to choose a business life. Among these was the preference for an unmarried life to wifehood and motherhood with small financial resources. An inherent aversion to the sacrifices of early married life and to maternity was also mentioned as an impelling force in the selection of work outside the home. He believed

that the women themselves, with their keen perceptions, would ultimately solve the problem and adjust themselves to the changed conditions.

The Place of Women in the Modern Business World as Affecting Health.—Dr. L. Duncan Bulkley claimed that it was not necessarily the work which undermined health, but rather the trying to work hard during the day and dissipating in the evening; not the load that killed, but the pace taken. He regarded it a blessing in disguise when the money earned was needed for the family or if other reasons demanded early bed hours. He thought the greatest field of philanthropy in connection with the subject was in education along the lines of true hygiene and proper modes of life.

Women in the Business World as Affecting Health and Morals.—Dr. Norman Bridges of Los Angeles did not believe that a business woman's experience unfitted her for a domestic life, and expressed his conviction that such an experience enhanced her power and efficiency as a useful social unit. Neither did he believe that her health was impaired unless she worked for very low wages and under depressing circumstances. To the claim that a business life detracted from feminine charm and innocence and led to boldness, he replied that boldness was a matter of temperament and native tendency not greatly influenced by conditions of occupation; and that a business life did not impair either charm or innocence, unless those words stood for ignorance and uselessness, which was often their real meaning. Neither did he believe that a business life tended to immorality. When a woman in business went wrong he believed it more often the result of starvation wages than of the fact of working. He thought that many girls in grinding clerkships would act wisely if they would take domestic service, whereby they would have less physical and mental fatigue and more comforts and money. To the argument that a woman should marry and make a home Dr. Bridges responded that, in the first place, this was manifestly impossible, and, in the second place, it was the woman's own affair. While the single business woman always, and the pampered rich woman often, failed to perpetuate the race, he claimed that the business woman was much less to blame than the married woman.

Female Labor as a Factor in Social Life.—Dr. A. L. Benedict of Buffalo submitted statistics bearing upon this phase of the subject, and showed that higher female labor involved a total of about 60,000 for the whole country. He referred to the increase of lower grades of female labor in offices, stores, factories, etc., which caused a scarcity of domestic help and did not fit poorer women so well for married life.

The Place of Women in the Modern Business World as Affecting the Future of the Race.—Dr. Otto Juettner of Cincinnati presented a paper bearing upon this part of the subject.

The Influence of Modern Methods of Education Upon Women.—Dr. George H. Hoxie of Kansas City said that a satisfactory home life depended primarily upon the physical fitness of the woman and the man. Motherhood considered from the medical standpoint was purely a physical matter. The other chief factor in the marital relation was mentioned as the religious or moral one. It was stated that physical and religious training needed to be as carefully systematized as the intellectual, but the present tendency in American education was to elevate the intellectual training into the position of primal importance and to make concession to the demand for physical and religious training by tolerating spasmodic and unsystematized ebullitions of individual notions. Because of overenthusiasm in their intellectual training the brightest women of the present generation had their nervous systems developed one-sidedly, and many physical ills resulted, hindering the happiest marital relation and the fullest reproduction of the species. The author believed that the schools would be benefited by securing greater permanency in the ranks of the teachers and some medical training in the ranks of the superintendents and principals.

Dr. Helen C. Putnam, in opening the discussion, claimed the right for all to develop their abilities in the preferred directions for the service of humanity. In order that good women might select good fathers for their children, she thought there should be the same attention paid to the moral and educational development of men as was made possible for women. She recognized the influence of women in furthering in a quiet way the work of the American Sanitary and Moral Prophylaxis Society. She thought, however, it might be desirable for woman's influence to be extended into the matter of woman's suffrage, thus giving her the right of selection of proper teachers and desirable municipal officers. She emphasized the need in the curriculum of public schools of a department of hygiene.

Dr. Emma B. Culbertson of Boston believed that the whole question could only be solved by the business men and women working together in a spirit of harmony and cooperation and upon an impartial basis. She called attention to the overwork required in the case of women school teachers, and believed there should be more attention paid to the adjustment of school matters, in which the endeavor should be made to keep them free from political interest. In this connection it was suggested that woman suffrage might be of value. She did not believe that race degeneracy in America was confined to the women, and thought the standard would soon be elevated with the presence of fathers of the proper type.

Dr. Edward Jackson of Denver called attention to the difference in the performance of work done now and that of a generation ago. This change in plan naturally necessitated a change in the occupations of the sexes.

Dr. John H. Tressel of Alliance spoke of the more natural deterioration physically among boys than among girls, which he attributed to the tendency to dissipation on the part of boys. He thought that more attention should be given to the boys in the matter of sanitation and physical exercise.

Dr. Donly C. Hawley of Burlingon thought the great changes in the economic world at times made it desirable for women to enter into competition with men in business and professional life. He felt, however, that every effort should be made to induce women to fulfil their true function, which, in his opinion, was that of wife and mother. He thought the effort should be made in school and business life to have a girl or woman remain at home for the few days of her menstrual period.

Dr. Florus F. Lawrence of Columbus thought the home should be made so attractive that girls might not desire to enter positions heretofore considered to belong to men.

Dr. Ward of California said that his experience as a teacher convinced him that women in professional work could be relied upon for the highest standards and absolutely without variation or compromise. So much as this could not be said for the men. He admitted that there were many professional men striving for the highest ideals but that on the other hand there were those ready to debase the profession for some personal advantage. He believed that the college women would be the ones in the next generation shown to be the leaders in women's work and he expressed his confidence that they would solve the question according to right.

An amendment to the Constitution was adopted providing for the election as Associate Members of those who were not physicians, but who had the required preliminary degree, and who were working along sociological, educational, and other scientific lines.

Officers.—The following officers for the ensuing year were elected: *President,* Dr. Helen C. Putnam, Providence; *Vice-Presidents,* Drs. Charles S. Sheldon, Madison; L. Harrison Mettler, Chicago; Joseph K. Weaver,

Norristown; Norman Bridges, Los Angeles; *Secretary and Treasurer*, Dr. Charles McIntire, Easton; *Assistant Secretary*, Dr. Alexander R. Craig, Philadelphia.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 21, 1908.

The President, Dr. John A. Wyeth, in the Chair.

The evening's program was devoted to a symposium on anesthesia.

The Hospital and the Professional Anesthetist.—Dr. A. T. Bristow read this paper. (See page 260.)

General Anesthesia on the Basis of the Principle of Adapting the Boiling Point of the Anesthetic to the Temperature of the Body (Schleich).—Dr. Willy Meyer read this paper. (See page 261.)

Anesthesia at St. Luke's Hospital.—Dr. Robert Abbe read this paper. (See page 263.)

The Administration of Anesthetics at Mt. Sinai Hospital; Notes from a Surgical Standpoint.—Dr. Howard Lilienthal read this paper. (See page 264.)

Rectal Anesthesia at Roosevelt Hospital.—Dr. W. S. Sutton addressed the members of the Academy for Dr. J. A. Blake and Dr. George E. Brewer. They believed that the term colonic anesthesia was a more correct one than rectal anesthesia. They gave the report on 100 cases, 52 males, and 48 females. There were 91 ward patients, and 9 private. The ages ranged from two to seventy-seven years, and there were a large number of patients at both extremes. The classification of their cases were interesting: There were 31 operations for tumors of the neck; 9 breast amputations; 8 operations for goiter or thyroid gland cyst; 6 craniotomies; 5 resections or suture or osteotomy of inferior maxilla; 5 corrections of old fractured limbs; 4 partial excisions of tongue; 4 cases of staphylorrhaphy; 3 tracheotomies; 3 mastoid operations; 2 operations for inguinal hernia; 2 operations for the removal of parotid tumors; 2 resections or osteotomies of superior maxilla; 2 removals of the Gasserian ganglion; 2 skin grafts; 1 orchidopexy; 1 operation for hydrocele; 1 appendectomy; 1 nephrotomy; 1 for Ludwig's angina; 1 enucleation of the eye; 1 resection of the knee; 1 cervical laminectomy; 1 operation for axillary adenitis; 1 excision of sternocleidomastoid; 1 plastic operation for stricture of the esophagus; 1 laryngectomy, and 1 neurorrhaphy. The average time of colonic anesthesia was fifty-three minutes. The average consumption of ether was 112 c.c. per hour. The number of patients having morphine, scopolamine, or both, was 12. The number having forms of supplementary anesthesia was 43. The number in which oxygen was used as the vehicle was 25. The number that belched gas from the stomach was 12. The number that showed perspiration was 18. The number that vomited or regurgitated was 43. The number that had abdominal pain was 12. The number that has blood in the stools as the result of this method was 5. The following were the points given in favor of colonic anesthesia: (1) The freedom of the operative field from contamination by the anesthetic. (2) The ability to maintain smooth and continuous anesthesia. (3) The uniform depth of the anesthesia, causing a light narcosis and a saving of the ether. (4) The lessening of the pharyngeal and bronchial secretion and of tonic contraction or troublesome relaxation of the jaw muscles. (5) The ability to administer oxygen without interrupting the anesthesia. (6) The lessened loss of body temperature because of diminished sweating and ether refrigeration. (7) The saving of ether. (8) The reduction of postoperative nausea and vomiting. There might be regurgitation without nausea. The points against this method were (1) an occasional postoperative occurrence of hemorrhage from the bowel; (2) an occasional difficulty in maintaining profound anesthesia.

The indications for colonic anesthesia were: (1) Operations on or about the respiratory tract (head, neck, and chest), especially those which laid open the mouth, pharynx, larynx, or trachea. (2) Operations on patients in whom ether absorption must be minimized on account of lung, heart, or kidney lesions. (3) Operations in cases already suffering from respiratory embarrassment.

The contraindications were: (1) Operations in cases with any inflammation of the intestinal tract. (2) Abdominal operations except those on the bladder or kidney. In such cases the distended colon tended to force the bladder or kidney into the operative field. (3) Operations in cases with markedly incompetent sphincter ani, or with large complete fistula in ano. (4) General emergency operations. Dr. Sutton then demonstrated the apparatus used and told of the preparation of the patient, the administration of the gas, and the after treatment. He also spoke of the development of the apparatus.

The Anesthetic at the Hospital for the Ruptured and Crippled.—Dr. V. P. Gibney read this paper. (See page 266.)

Anesthesia at the Harlem Hospital.—Dr. W. H. Luckett made this report. Letters from members of the surgical staff were read in which each member told of his favorite anesthetic.

Anesthesia at Bellevue Hospital.—Dr. George Woolsey read this paper. He said that the question of the administration of anesthesia at Bellevue Hospital was complicated by the fact that there were eighteen general or special surgeons who might vary the practice in the use of anesthetics to suit their own preference. A circular letter was sent to these several surgeons and replies were received from fourteen, from which, and his knowledge of the conditions at Bellevue, the following conclusions were drawn: Ether was the favorite anesthetic of all, but the method of giving it varied. The majority (eight) commenced anesthesia with nitrous oxide gas, and one other used it occasionally; two did not use it, and three did not as a rule. The drop method appeared to be the favorite method of giving ether, being used most by five and equally with the Bennett inhaler by two. Two preferred the open method without specifying what form of open apparatus they use; one used the closed and open methods equally, and two preferred the Bennett inhaler. The variety of methods was shown by the fact that one surgeon used Keith's modification of Clover's inhaler. From this summary, and his knowledge of the practice in the past, it appeared that the use and preference of the open method, and especially the drop method, had increased very much of late, at the expense of the closed methods. In this connection it should be remembered that the conditions at Bellevue differed somewhat from those at many other hospitals in the relatively greater number of alcoholics among those who were anesthetized. The use of the closed methods in this class of patients required more skill and was attended with more difficulty. The conditions attending the use of anesthesia at Bellevue were not and could not be ideal. The ideal method was to have a professional anesthetist for every anesthesia. Apart from the expense and impracticability of this, another difficulty lay in the fact that the house staff must be taught the practice of anesthesia so as to become fairly proficient in its use for future necessities. For some years past professional anesthetists had been employed at Bellevue to teach the house staff and no member of the latter was allowed to give anesthesia alone until he had been qualified by the anesthetist. Formerly there was but one instructor on duty at a time, and he could not give the time to instruct thoroughly the staff of each of the four divisions; now there was an instructor for each division.

An inquiry as to whether this instruction worked well or not gave the following: Six thought it worked well; four fairly well; one not well; and two thought that little

instruction was really given, or perhaps received. One surgeon replied that the best instruction was given by the older members of the house staff. Dr. Woolsey's own experience had been that the staff of another hospital, with which he was connected and where no other instruction was given, had always used the Bennett inhaler better than the staff at Bellevue. The situation at Bellevue was more difficult, as had been said, on account of the large number of alcoholics. As to other forms of anesthesia, chloroform was used rarely, if ever, by thirteen; and only one replied that he used it, and would use it more if he had competent men to give it. The occasional cases where it was used included young children, pulmonary complications, short operations, operations on mouth, face, and neck, cases where ether was contraindicated, and sometimes at the beginning of an operation. Nitrous oxide gas alone was used by one, occasionally by four, and not at all by nine. Here, too, the inexperience of the staff in giving gas, except as a preliminary to ether, deterred many from using it in cases in which it was now more generally used than formerly. Spinal anesthesia was not used by ten, and occasionally by four, especially in cases of gangrene and in some old subjects where ether was distinctly dangerous, at least as given by the average interne. On the other hand local anesthesia was used quite extensively, especially for minor operations, but also for a variety of major operations as well. A year or two ago the trustees of Bellevue and the allied hospitals passed a regulation requiring the presence of an attending or assistant surgeon whenever general anesthesia was employed. Whether this regulation had increased the use of local anesthesia more than it would naturally have increased was an open question. In answer to his inquiry as to this point six thought that it had not increased its use, four that it had, and four did not know. As he compared the present practice with that of three to five years ago, the most noticeable changes were the stricter regulations as to the use of general anesthesia, and the growing preference for the open method, and especially the drop method, of administering ether.

Nitrous Oxide and Oxygen as an Anesthetic Agent; Notes on the Value of Warming of Vapors of Ether and Chloroform.—Dr. James T. Gwathmey read this paper. He believed that from every standpoint the ideal routine administration of the anesthetic should be about as follows: (1) In addition to the usual preparation, the patient's nerves should be controlled by previous medication in either of the two following ways: (*a*) A suitable dose of morphine according to the age and conditon of the patient; (*b*) an enema of seven ounces of saline and one of whiskey one-half hour before the operation. The patient would then come to the table in a suitable frame of mind. (2) The anesthesia should be commenced with nitrous oxide and oxygen, or nitrous oxide and air, and continued until full surgical anesthesia was reached with this agent, and then the ether chamber should be turned on gradually and slowly. In this way there would be no swallowing in the first five minutes. (3) The method of administration should now be changed to the closed inhaler and the anesthesia deepened by rebreathing. This should be continued until the whole system had been thoroughly stimulated by the ether. (4) A change should now be made to warm chloroform, given either by the vapor method, or drop by drop. (5) This change to chloroform should be made when the patient was only lightly under ether. Care must be taken not to allow the patient to come out sufficiently to exhibit any rigidity of the muscles. On the other hand, the narcosis should not be deepened unnecessarily. (6) As the operation was drawing to a close a warm saline enema should be given and the anesthesia should be so lightened that the patient would exhibit signs of consciousness as the bandages were being applied. (7) This enema should be repeated every few hours as required.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Nebraska State Board of Health Examinations.

Lincoln, Neb., May 27, 28, 29, 1908.

ANATOMY.

1. Give a general description of the skin; describe the layers, and the special structures and appendages.
2. Give brief description of the animal cell.
3. Describe the mastoid portion of the temporal bone.
4. Discuss briefly the thyroid body.
5. Give the peritoneal relations of the colon.
6. Give the peritoneal relations and connections of the bladder.
7. Give the origin of the vessels of the uterus and the ovaries.
8. Briefly describe the shoulder joint and name its ligaments.
9. Name all the orifices of the diaphragm, also the structures passing through each orifice.
10. Give the origin and insertion of the muscles of the abdominal walls.

PHYSIOLOGY.

1. (*a*) Give the varieties of cartilage. (*b*) Give distribution. (*c*) State how cartilage is formed and nourished.
2. Describe the normal heart sounds and give the area of maximum intensity of the sounds of the chest wall.
3. Describe the sphygmograph and make a sphygmographic drawing of a normal pulse, also a drawing of a pulse in mitral insufficiency.
4. What are the accepted theories as to the origin of the white blood corpuscle; the red blood corpuscle; state the relative proportion of the white and red corpuscles in the human body.
5. Name the digestive ferments and give the origin and action of each.
6. Explain in detail how the functions of the auditory organs are performed.
7. Give the functions of the kidney; state what causes the acidity of the urine.
8. Name the ductless glands of the body and give the latest theory of the function of each gland.
9. Describe the process of ovulation.
10. Explain arterial tension and show by what nervous and mechanical agencies it is maintained.

CHEMISTRY.

1. Define chemical action, physical action; give examples of each.
2. What is the atomic theory?
3. Give the average amount and composition of normal urine voided by an adult in twenty-four hours.
4. Name and describe the method of using two tests for the detection of sugar and albumin in the urine.
5. Name the enzymes of the pancreatic juice and give the functions of each one.
6. Name six metals and six nonmetals.
7. How would you detect arsenic in the contents of the stomach?
8. Why is the administration of albumen useful in poisoning?
9. Where is oxygen found in the human body and what are its important uses in the animal economy?
10. Give the common name and properties of mercurous chloride; of corrosive sublimate. Mention an easily applied test that will distinguish one from the other.

MATERIA MEDICA AND THERAPEUTICS.

1. Write a prescription for the following: Lithemia, dysuria, chorea.
2. Name the impurities in water that may cause diarrhea.
3. Mention and describe the diseases of animals that are communicable to man and state the means to be employed for their prevention in man.
4. Under what conditions would you prescribe the following: Capsicum, strophanthus, iodine, nux vomica, tr. aconite?
5. What is the composition of compound cathartic pill, brown mixture, Fowler's solution, and Donovan's solution?
6. Diphtheria antitoxin: how and when is it used; give doses, prophylactic and curative; how is it obtained?
7. How would you manage a case of typhoid fever; how prevent its spread?

8. What are the therapeutic uses of mineral acids? Name five.
9. How would you manage a case of tuberculosis? What precautions would you employ to prevent its spread?
10. Give the adult dose of the following drugs: Strychnine, atropine, adrenalin, nitroglycerin, belladonna, codeine; sulphonal, morphine, acetanilid, hyoscine, and ether.

PATHOLOGY.

1. Give the pathology of aneurysm.
2. Define myomata, neuromata, angiomata.
3. What part of the cord is involved in locomotor ataxia? Give the pathology of same.
4. Differentiate between osteomyelitis and inflammatory rheumatism.
5. Give the pathology of typhoid fever.
6. Differentiate between scarlet fever and measles.
7. Give the etiology and pathology of pericarditis and name the different forms.
8. Describe fibrinous pneumonia.
9. What is hydrosalpinx? Give its pathology.
10. Give the pathology of simple acute catarrh of the intestines.

PRACTICE.

1. Give etiology, diagnosis, treatment, and prognosis of erysipelas.
2. What are the causes and give treatment of palpitation of the heart.
3. Differentiate the classes of croup and give the treatment for each.
4. Define neurasthenia and give etiology, symptomatology and treatment.
5. Give etiology and treatment of eclampsia infantum.
6. Give the diagnosis and treatment of lobar pneumonia.
7. Diagnose and outline the treatment for obstruction of the cystic duct; and of the common bile duct.
8. What is herpes zoster? Give the cause and treatment.
9. Give the treatment of chronic follicular pharyngitis; give treatment of acute catarrhal laryngitis.
10. Give etiology, characteristic symptoms, and treatment of acute chorea.

OBSTETRICS.

1. (*a*) Describe the changes that take place in the breasts as a result of pregnancy. (*b*) What disease of the breasts is most apt to follow labor and what prophylactic measures would you adopt to prevent it?
2. Give the etiology, symptoms, sequelæ, and treatment of septic endometritis (nonspecific).
3. What is subinvolution? Give symptoms and treatment.
4. What is the treatment of placenta prævia, hemorrhages occurring before full term? How would you manage it?
5. Give the causes, symptoms, and management as best understood and practised at present, of albuminuria of pregnancy.
6. (*a*) Give the causes of retroversion and retroflexion of the uterus. (*b*) Give the differential diagnosis between the two. (*c*) Give the treatment for each.
7. What are the symptoms of the so-called puerperal insanity? Give an outline of its treatment.
8. Name three of the most common causes of premature birth.
9. How would you diagnose the presence of a ruptured uterus and what treatment is called for?
10. Give the treatment for gonorrheal vaginitis.

SURGERY.

1. Differentiate between epithelioma and lupus.
2. What symptoms would indicate a rupture of the middle meningeal artery, following an injury to the head, and by what superficial landmarks would you locate it?
3. Differentiate between eczema, dermatitis, and syphilis.
4. Give some of the chief causes of delayed union in fractures and the treatment you would adopt for each cause.
5. Describe the several forms of corneal ulcer; their causes and treatment.
6. Give diagnosis, course, and treatment of gonorrheal arthritis.
7. Give the indications for tracheotomy and describe how same is performed.
8. What is synovitis? Give the causes, symptoms, and treatment.
9. What is phlebitis? Give causes, symptoms, and treatment.
10. Give the indications for the removal of the prostate gland.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

NEBRASKA STATE BOARD OF HEALTH EXAMINATIONS.

Lincoln, Neb., May 27, 28, 29, 1908.

ANATOMY.

5. The *oscending colon* is generally covered with peritoneum on its anterior surface and the two sides; the posterior surface is generally uncovered.

The *transverse colon* is completely covered with peritoneum except on the first few inches of the posterior surface.

The *descending colon* is generally covered with peritoneum on its anterior surface and sides only; the posterior surface is destitute of peritoneal covering.

In the *sigmoid flexure* the lower or pelvic portion is entirely covered by peritoneum; the upper or iliac portion is generally only covered by peritoneum on its anterior and two lateral surfaces.

6. The superior surface of the bladder is covered by peritoneum. "From each lateral border the peritoneum passes *(lateral false ligaments)* to the pelvic wall, lining a groove *(parovesical fossa)* which is present on each side when the bladder is empty. Anteriorly the peritoneum passes *(anterior false ligaments)* over the urachus to the anterior abdominal wall, at the upper border of the symphysis when the bladder is empty; two or more inches higher when the bladder is full. Along the posterior border the peritoneum passes to the rectum or uterus, forming a fold *(posterior false ligament)* at each side of the rectovesical or uterovesical pouch.

The base is chiefly fixed by the *true ligaments*, processes of the pelvic fascia reaching in front from the pubis, and laterally from the sides of the pelvis. It is fixed to the anterior abdominal wall above by the urachus. It is also fixed by fibrous tissue to the ureters, seminal vesicles, and vasa deferentia (or vaginal walls).

7. The *uterus* is supplied by the uterine artery (from the internal iliac) and the ovarian artery (from the aorta).

The *ovaries* are supplied by the ovarian arteries (from the aorta).

9. The *orifices of the diaphragm* are: (1) The aortic, transmitting the aorta, vena azygos major, and the thoracic duct; (2) the esophageal, transmitting the esophagus, pneumogastric nerves, and some small esophageal arteries; (3) the opening for the vena cava, transmitting the inferior vena cava, and small branches of the right phrenic nerve; (4) the right crural, transmitting the right splanchnic nerves; (5) the left crural, transmitting the left splanchnic nerves and the vena azygos minor.

PHYSIOLOGY.

2. There are two normal heart sounds which follow in quick succession, and are succeeded by a pause. The first, or systolic, sound is dull and somewhat prolonged; the second, or diastolic, sound is sharper and shorter. The sounds may be expressed by the syllables *lubb—dup*.

The first sound is heard best at the apex beat in the fifth left intercostal space; the second sound is heard best over the second right costal cartilage.

4. The white blood corpuscles are supposed to be made in the lymphatic glands; the red ones in the red bone marrow.

The proportion of white to red corpuscles is about 1:700.

5.

DIGESTIVE FERMENTS.	ORIGIN.	ACTION ON FOOD MATERIALS.
Ptyalin.	Saliva.....	Changes starches into dextrin and sugar.
Pepsin.	Gastric Juice....	Changes proteids into proteoses and peptones in an acid medium.
A curdling ferment.		Curdles the casein of milk.
Trypsin.	Pancreatic Juice.	Changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; in an alkaline medium.
Amylopsin.		Converts starches into maltose.
Steapsin.		Emulsifies and saponifies fats.
A curdling ferment.		Curdles the casein of milk.
Invertin.	Intestinal Juice..	Converts maltose into glucose.

6. "The waves of sound are gathered together by the pinna and external auditory meatus, and conveyed to the membrana tympani. This membrane, made tense or lax by the action of the tensor tympani and laxator tympani muscles, is enabled to receive sound waves of either high or low pitch. The vibrations are conducted across the middle ear by a chain of bones to the foramen ovale, and by the column of air of the tympanum to the foramen rotundum, which is closed by the second membrana tympani, the pressure of the air in the tympanum being regulated by the Eustachian tube. The internal ear finally receives the vibrations, which excite vibrations successively in the perilymph, the walls of the membranous labyrinth, the endolymph, and, lastly, the terminal filaments of the auditory nerve, by which they are conveyed to the brain." (Brubaker's *Physiology.*)

7. The function of the kidney is to separate the urine from the blood, and to excrete urea.

The acidity of the urine is due to the presence of acid sodium phosphate.

8. The *ductless* glands are: The spleen, thymus, thyroid, parathyroids, suprarenals, carotid, coccygeal, pituitary, and pineal glands.

The *function of the spleen*: The following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blood corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin.

The *function of the thymus* is not settled; it is said: (1) To be a blood forming organ; (2) to have influence on growth and nutrition; (3) in hibernating animals it is supposed to store up materials which can be utilized during the period of inactivity.

The *function of the thyroid* is not definitely settled; (1) it has some trophic function; (2) it is supposed to antagonize toxic substances; (3) it produces an internal secretion.

The *function of the suprarenals* is not definitely settled; they produce an internal secretion which is probably necessary to life; it is supposed that they are able to destroy or remove some toxic substance produced elsewhere in the body.

The function of the *other* ductless glands is unknown. They all, or nearly all, furnish an internal secretion.

CHEMISTRY.

1. "A bar of soft iron may be made to emit light when heated, or sound when caused to vibrate, or magnetism when under the influence of an electric current. Under the influence of these *physical forces* the iron suffers no change in composition, and, on cessation of the action of the inciting force, the iron returns to its original condition. But if the iron be heated in an atmosphere of oxygen, both the iron and a part of the oxygen disappear, and a new substance, a new chemical species, is produced, having properties of its own, different from those of either the iron or the oxygen. In this case there has been *chemical action*, causing change of composition, as the new substance contains both iron and oxygen. The result of such action is, moreover, permanent, and the new product continues to exist, until modified by some new manifestation of chemical action." (Witthaus' *Manual of Chemistry.*)

2. The atomic theory regards matter as not being infinitely divisible, but as being composed of indivisible particles called atoms. Dalton, by ascribing to each atom a relative weight as compared with the weight of other atoms, was able to explain and produce reasons for all the observed numerical laws of chemical combination.

3. The following table (from Dunglison's *Medical Dictionary*) gives the average composition of normal urine:

	(Parts in 1000.)		Voided Per Day	
			Grains	*Grams*
Water	950.00			
Urea	28.00		520.80	35.00
Uric acid	0.60	Organic	11.16	0.75
Hippuric acid	0.35	matter	6.51	0.44
Creatinin	0.65	37.60	12.09	0.81
Extractives	8.00		148.80	10.00
Sodium chloride	8.00		148.80	10.00
Phosphoric acid	2.00		37.20	2.50
Sulphuric acid	1.25	Inorganic	23.45	1.56
Lime (CaO)	0.25	matter,	4.65	0.31
Magnesia (MgO)	0.30	12.40	5.58	0.37
Potash (K_2O) and soda (Na_2O)	0.60		11.16	0.75
Total	1000.00		930.20	62.49

The average amount of urine voided in twenty-four hours is about fifty ounces.

4. Two tests for the detection of sugar in the urine: The urine should first be tested for albumin. If this be present, it should be removed by heating the urine to near the boiling point, and filtering from the coagulum.

(1) *Fehling's test:* Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

(2) *Boettger's test:* Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by the dark or black color of the bismuth powder, the litharge retaining its natural color. (From Witthaus' *Essentials of Chemistry.*)

Two tests for the detection of albumin in the urine: "The urine must be perfectly clear. If not so, it is to be filtered, and if this does not render it transparent, it is to be treated with a few drops of magnesia mixture and again filtered."

I.—*The heat test:* "The reaction is first observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3."

II.—*Heller's modification of the nitric acid test:* "Place in a test-tube a layer of HNO_3 about 2 centim. in thickness; then, with a pipette, carefully float upon the surface of this a layer of the urine in such a manner that the liquids do not mix. If albumin be present, a cloudy ring appears *at* the point of junction of the two layers, the borders of the cloud being sharply defined. A cloudy ring may be formed by the presence of an excess of urates, but in this case it is not *at*, but *above*, the point of junction of the layers, and its upper border is not sharply defined, but fades off gradually." (Witthaus' *Essentials of Chemistry.*)

5. See above, physiology, Question 5.

6. *Six metals*: Mercury, copper, zinc, lead, gold, silver.

Six nonmetals: Hydrogen, oxygen, nitrogen, fluorine, chlorine, sulphur.

7. *Arsenic* in the stomach contents can be detected by *Reinsch's test*, as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

8. The administration of albumin is useful in many cases of poisoning, because the albumin forms more or less insoluble compounds with most of the metallic salts, mineral acids, corrosive alkalies, and some of the alkaloids.

9. Oxygen is found in the human body in the blood plasma, and in combination in almost every tissue of the body.

Its uses in the animal economy are: To maintain respiration, aerate the blood, oxidize the tissues, and thus to supply heat and energy. It supports life and combustion.

10. *Mercurous chloride* or *calomel* is a heavy, white powder; amorphous; tasteless and odorless; it is insoluble in cold water and in alcohol, and very slightly soluble in boiling water; when exposed to the light it becomes discolored (first yellow, then gray) and partially decomposed; it sublimes without fusing; it is incompatible with the mineral acids, with the alkaline chlorides, bromides, and iodides.

Corrosive Sublimate is heavy, white and crystalline; it has a strong, acrid, styptic taste, and is soluble in water, in alcohol, and in ether; it is decomposed by exposure to light.

They can be easily distinguished by their solubility.

MATERIA MEDICA AND THERAPEUTICS.

1. *For Lithemia*:

℞ Potassii acetatis.
Potassii bitartratis.
Potassii citratis aa ℥ss.
Aquæ destillatæ q.s. ad ℥viij. Misce.
Signa:—One tablespoonful in half a glass of water after each meal.

For Dysuria: If due to acute cystitis, the above prescription will do here also.

For Chorea:

℞ Chloralis hydratis, ℥ij.
Sodii bromidi, ℥iv.
Aquæ destillatæ, q.s. ad ℥ij. Misce.
Signa:—One teaspoonful in water, every five hours, for three doses.

2. The impurities in water that may cause diarrhea, are: Suspended mineral matters, suspended animal (fecal) and vegetable matters, fetid gases, and an excess of dissolved nitrogenous organic matter.

3. "Among the most common of the diseases and parasites of animals, which are communicable to man, are: (1) Glanders, a disease of the genus *Equus*, generally fatal when contracted by man; (2) anthrax, a disease of horses, cattle, sheep, and swine, appearing in man either as malignant pustule or as internal anthrax, and often fatal; (3) tuberculosis, a disease common in cattle and swine, but also occurring in horses, sheep, goats, dogs, poultry, cage birds, and menagerie animals; (4) rabies, a disease of the genus *Canis*, communicable to all warm-blooded animals and to man; (5) epizootic aphtha, commonly known as foot-and-mouth disease, a very infectious malady of cattle, sometimes communicated to the consumers of the milk of diseased cattle; (6) *Cysticercus bovis*, found in cattle, is the larval form of the tapeworm of man known as *Tænia saginata;* (7) *Cysticercus cellulosæ*, found in swine, is the larval form of the tapeworm of man known as *Tænia solium;* (8) the *Trichina spiralis*, a common parasite of swine, may develop in man and sometimes produces fatal results; (9) the *Echinococcus* found in the lungs, liver, and other organs of the meat-producing animals is the cystic phase of the *Tænia echinococcus* of the dog.

"It is evident that the most satisfactory way of protecting man from this source of danger is to eradicate these diseases and parasites so far as possible from the domesticated animals. As complete eradication cannot be accomplished for many years and in some cases not at all, there must be constant efforts for repression and control. People must be made familiar with the dangers; too close association with animals should be avoided; the inspection of meat and of dairy cows should be universal; swine flesh should be well cooked; hides, wool, and hair, often infected with the anthrax bacillus, should be handled with suitable precautions; biological products used for the prevention or cure of human diseases should be surrounded with every safeguard to avoid contamination." (*Reference Handbook of the Medical Sciences.*)

5. *The compound cathartic pill* consists of:—Calomel, about one grain; compound extract of colocynth, about one and a quarter grains; resin of jalap, about half a grain; and gamboge, about one-quarter of a grain.

Brown mixture is compound mixture of glycyrrhiza, and contains extract of glycyrrhiza, syrup, acacia, wine of antimony, spirit of nitrous ether, camphorated tincture of opium, and water.

Fowler's Solution is liquor potassii arsenitis, and contains arsenic trioxide, potassium bicarbonate, compound tincture of lavender, and water.

Donovan's Solution is liquor arseni et hydrargyri iodidi, and contains arsenic iodide, mercuric iodide, and water.

7. To prevent the spread of typhoid, each household should boil all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put *in* water or other drink or food; flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed, and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over.

9. Suitable measures for preventing the spread of tuberculosis would include: Careful disinfection or burning of sputum, etc.; avoidance of spitting in public places; plenty of fresh air and sunlight; an abundance of good and easily digested food; the proper inspection of food supplies; the avoidance of kissing; and reporting of cases to the proper health authorities, and cooperation with them.

10. Adult doses: Strychnine, gr. 1/64; atropine (sulphate), gr. 1/160; adrenalin, ♏xx. of a one per cent. solution; nitroglycerin, one minim of a one per cent. solution; belladonna (alcoholic extract of), gr. 1/5; codeine, gr. 1/2; sulphonal, gr. xv; morphine, gr. 1/4; acetanilid, gr. iv; hyoscin (hydrobromate), gr. 1/128; ether, ♏xv.

PATHOLOGY.

3. In *locomotor ataxia* the posterior columns of the spinal cord and the posterior nerve roots are involved.

The posterior columns of the spinal cord are gray and shrunken, and show considerable overgrowth of connective tissue in the columns of Goll, Burdach, and Lissauer; this process extends upward from the lumbosacral region; the posterior nerve roots degenerate and become atrophic. The meninges over the affected parts become opaque and adherent. Some of the cranial nerves may also atrophy, notably the optic, but also the motor oculi and vagus.

The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective titssue, and sometimes congestion; the spinal ganglia may be affected.

4. In *ostcomyelitis* the shaft of the bone is usually attacked, the fever is moderate only, there are no acid sweats, and heart lesions are not usually present.

In *rheumatism* the joints are usually attacked, and more than one may be involved, the fever may be high, acid sweats are present, and the heart is usually involved.

6. In *scarlet fever* the eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type, the lymphatics in the neck may be swollen, and there is sore throat.

In *measles* the eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present.

PRACTICE.

2. Palpitation of the Heart. *Causes*: Anemia, neurasthenia, fright, hysteria, anxiety, indigestion, alcohol, tea, coffee, tobacco, excitement, unusual physical exertion, organic disease of the heart.

Treatment: If possible, remove the cause; institute proper hygiene and diet; moderate exercise, abstention from excesses of any kind, warm baths, regular hours, and rest are necessary; aconite, iron, strychnine, and bromide of potassium have each been recommended; electricity, Weir-Mitchell rest cure, and a mild mountain climate have been suggested.

3. *Membranous or True croup* is either laryngeal diphtheria or a streptococcus infection. In either case there is a prior stage of malaise, accompanied by chills, fever, and sore throat. The fever may become very high. A membrane forms, in which are found the Klebs-Loeffler bacillus or streptococci. *False or Spasmodic croup* generally comes on suddenly, at night. There is no appreciable fever, no previous malaise or sickness, and often the patient is asleep again by the time the physician arrives. There is frequently a thick tenacious mucus, but neither Klebs-Loeffler bacilli nor streptococci are present. It is entirely a local disturbance.

5. *Causes of eclampsia infantum* are: "Overeating, especially of indigestible food; rachitis, debility from exhausting diarrheal diseases; high fever, especially at the onset of the acute specific infections; very seldom dentition, phimosis, and acute middle-ear inflammation; injuries to the brain at birth, infantile hemiplegia, meningitis, and tumor of the brain; rarely of spinal cord disease.—(From Butler's *Diagnostics of Internal Medicine.*)

OBSTETRICS.

1. (*a*) The changes that take place in the breasts as a result of pregnancy: The breasts increase in size and vascularity, and feel knotty; the areola becomes darker and wider; a secondary areola develops; the nipple and glandular follicles around it become larger; fluid can sometimes be squeezed out of the nipples, especially towards the end of pregnancy.

(*b*) Following labor, mastititis, due to septic infection, may occur. This can only be prevented by the best antiseptic precaution; the breast must be kept clean, the nipple dry, and the parts are not to be touched by the patient, and only by the physician or nurse after the most thorough antiseptic precautions. The nipple should be kept clean by boric acid solution, and the breast should not be allowed to get engorged.

8. Three of the most common causes of premature birth: Syphilis, endometritis, and the abuse of drugs (oxytocics).

SURGERY.

I.

EPITHELIOMA.	LUPUS.
Cancerous.	Tuberculous.
Generally occurs in adults.	Generally occurs in young people.
Infiltrates the tissues, and may extend rapidly.	Spreads slowly, and may heal at one part while breaking down at another.
Glands are involved.	No glandular involvement.
Usually painful.	Not usually painful.
Cachexia is present.	No cachexia.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 5
Arizona*	Ancil Martin, Phoenix	Phoenix	Oct. 5
Arkansas*	F. T. Murphy, Brinkley	Little Rock	Oct. 13
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	Los Angeles	Dec. 1
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	Oct 6
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov. 10
Delaware	J. H. Wilson, Dover	Dover	Dec. 8
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	Oct. 13
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	Nov. 11
Georgia	E. R. Anthony, Griffin	Atlanta	Oct. 6
Idaho	W. F. Howard, Pocatello	Boise	Oct. 6

* No Reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State

District of Columbia.—In a new bill concerning the practice of medicine in the District of Columbia there is a requirement that the medical school from which the physician has been graduated must have a course of "four school years of at least nine months each."

Rhode Island.—In future candidates for the examination for license to practice medicine in this State will be required to have been graduated from a reputable medical college.

Pennsylvania.—Of 398 applicants for licenses to practise medicine in Pennsylvania at the recent examination, 362 passed the examination of the State Medical Board, and it is said that the papers made an excellent showing.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 8, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	411	137
Diphtheria	170	14
Measles	130	7
Scarlet Fever	89	2
Smallpox	—	—
Varicella	10	—
Typhoid Fever	107	20
Whooping Cough	23	12
Cerebrospinal Meningitis	10	6
Malarial Fever	—	—
Totals	950	198

Presence of Sudanophile Leucocytes in Diphtheritic Infection.—Luigi Banini has examined the sudanophile leucocytes in diphtheria as well as in cases of nondiphtheritic angina. He found these granules in the polynucleated and mononucleated leucocytes. They were present in considerable numbers in severe cases of diphtheria, especially when the glands of the neck were swollen. In cases of less gravity these granules were of less frequency. They were absent in nondiphtheritic cases. They diminish rapidly as the disease improves. The author believes that the formation of these granules is the result of the disease, and arises from degenerative phenomena. The finding of these granules is an indication of the gravity of the disease and the amount of intoxication, and indicates a bad prognosis when they are in large numbers.—*Rivista di Clinica Pediatrica.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service for the week ending August 7, 1908:

THE APPEARANCE OF HETEROPLASTIC TUMORS IN THE TRANSPLANTATIONS OF THE NEWGROWTHS OF ANIMALS.*

BY PROFESSOR DR. VON LEYDEN
AND
PROFESSOR DR. CARL LEWIN,
BERLIN.

EVER since the work of Hanau, of Moran, of Loeb, and especially of Jensen has made possible the transplantation of tumors in mice and in rats, the research workers of all lands have been carefully studying the conditions necessary for the origin and the growth of the transplanted tumors in these animals. Jensen, Ehrlich, Apolant, Loeb, Michaelis, and others all agree that the development of the transplanted newgrowth is due to the division of the cells brought over from one animal to the other, the stroma alone of the tumor being furnished by the tissues of the latter animal. Accordingly, these results support the view which was especially championed by pathologists even before the experimental work on tumors began, namely, that the transfer of tumors in animals did not occur through infection, but was in reality a transplantation of tissue, that is, the artificial production of metastases. No new tumors appeared, therefore, but the old ones continued their existence by the production of new cells. Of course, it seemed as if the results of the new research work had added but little to the solution of the tumor problem. Many points of interest in regard to newgrowths in human beings could be elicited by varying the rate of growth of the neoplastic cells that were experimentally transferred as well as the resistance of the animal tissues to the encroaching tumor tissues; the real essence of the problem involved in the production of malignant tumors remained as dark as before.

So much more surprising was the announcement made by Ehrlich and Apolant in the year 1904, telling of their observation of a mouse cancer which in the sixty-eighth transplantation assumed the appearance of a spindle-celled sarcoma. The sarcoma did not appear suddenly; at first the stroma became more cellular, simulating the usual appearance of a *carcinoma sarcomatosum;* gradually the epithelial elements of the original tumor disappeared and there remained a pure spindle-celled sarcoma which up to the present time has kept this acquired character. A communication from Loeb of New York followed the announcement of Ehrlich, the observation reported by him being similar to the one described above. In Loeb's case, however, the appearance of sarcomatous elements was observed as early as the second transplantation, the original epithelial elements of the tumor being overwhelmed by the newly appearing connective tissue very soon after the transfer of the newgrowth from one animal to another. So unusual were both these observations that at first it was thought that the original tumor was a mixed one, and even before the transplantation experiments contained the elements of both carcinoma and sarcoma. Ehrlich and Apolant, however, showed immediately that such an assumption was not justifiable. Otherwise it would be quite inexplicable why the sarcomatous part of the tumor should have stayed inactive for sixty-eight generations only then to take on a rapid and overwhelming growth. Loeb, in addition, made serial sections of the original tumor used by him, and could thus prove that not a particle of sarcomatous elements was to be found in it, and the new tumor must have appeared after the transplantation.

How was such a phenomenon, the appearance of a sarcoma in a carcinoma during transplantation, to be explained? It certainly could not be assumed that the cells of the cancer changed into the cells of the new connective tissue tumor, both Ehrlich and Loeb considering this explanation only to drop it immediately. Both authors are rather of the opinion that the sarcoma was due to a malignant degeneration of the stroma cells; that is, they assumed that the cells of the cancer had some stimulating or irritating effect upon the connective tissue cells of the animal to which the tumor was transferred which had the effect of producing malignant overgrowth of these cells. Both Ehrlich and Loeb believe that the stimulus effective in this way is chemical in nature. However, so exceptional was the observation of these authors that the occurrence was regarded as an extremely rare one by all other workers. Soon this view had to be abandoned because further experiments have shown that the process observed was more or less a regular event which had its source in the very nature of the cancer cell. Ehrlich and Apolant were enabled in a short time to report two more instances of sarcomatous change in a mouse carcinoma during the passage of the original tumor through a series of animals. Liepman succeeded in producing the same phenomenon in working with a tumor from our institute, and finally Bashford of London succeeded in showing that the change in the type of tumor was in fact due to the malignant metamorphosis of the connective tissue cells under the influence of the transplanted carcinoma cells. He had noted that the stroma cells usually degenerated in the transplantation of the mouse carcinoma up to the time of the appearance of a sarcomatous change, when a sudden increase in the stroma cells could be noted going on to the production of the new type of tumor.

All these observations were made in working with the tumors of mice, and, therefore, when the Berlin Institute for Cancer Research succeeded in noting the same process in rats the phenomenon

* From the Berlin Royal Institute for Cancer Research

assumed an even greater importance. The tumor under observation was a primary adenocarcinoma of the mammary gland of a rat. During the transplantation through the fifth generation of animals there developed in it a sarcoma while the original epithelial cells were still represented. In the further course of the experiments the epithelial elements disappeared altogether and there remained but the pure sarcoma elements in the tumor. The development of the sarcoma at the same time was not at all a uniform one. In some tumors there developed at first a *carcinoma sarcomatosum*, which retained its character through several transplantations until the epithelial elements began to disappear leaving the sarcoma alone in the end. Other tumors retained their carcinomatous character, while others still showed no traces whatever of the original epithelium. The sarcoma began to develop between the sixth and the twelfth generations of transplantations in the various animals and after the twelfth generation the carcinoma part of what was originally a pure adenocarcinomatous tumor disappeared completely and the new tumor could be transplanted further as a true sarcoma. Even then, however, this sarcoma was somewhat peculiar in type, the morphological character of the cells being quite variable. Some of the tumors presented only the appearance of a spindle-celled sarcoma, others showed an abundance of round cells, others still were of a mixed type in their morphological picture. Thus almost all types of sarcoma cells could be observed in the various specimens, with the exception of giant cells. The appearance of the cells, too, was quite inconstant in the course of further transplantations, a sarcoma which had the character of a spindle-celled tumor losing it in the course of the transfer and growing in another animal as a round-celled tumor. Thus it must be accepted that the tumor cells may change in form during the growth of a transplanted portion.

Still another important observation has been made in the Institute. We have already said that the original tumor discussed above was a primary adenocarcinoma of the mammary gland of a rat; neither its structure nor its site was in any way different from the same characteristics as observed in the tumors of mice involving the breast, the picture quite agreeing with the appearances so well described by Apolant. We were therefore very much surprised to see the appearance of a cancroid tumor in the third series of transplantations, the process of its development being quite similar to the one observed in the case of the sarcoma. The appearance of the cancroid came about gradually, so that in several series pure adenocarcinoma, cancroid, and mixed forms were growing side by side, in addition to the sarcomatous forms described above.

What were the causes that resulted in the appearance of the cancroid type of tumor? For an explanation we must assume that the same process which brought about the appearance of the sarcoma was concerned in the production of the cancroid tumor. The same causes were responsible for the gradual development of the cancroid as of the sarcoma, and in our opinion no metaplastic phenomena took place. To assume the latter we must consider it possible that an original adenocarcinoma could be transformed by metaplasia into a squamous tumor as well as into a sarcoma. Such a conception, however, opposes all the views usually held by pathologists, and we remember that during the discussion of this subject in the Berlin Medical Society Orth said that "if such a metaplasia of carcinomatous cells into those of sarcoma were granted then he would feel compelled to begin the study of pathological anatomy all over again." In this aspect of the subject we are in full accord with the views of Orth, for we likewise do not at all believe that any metaplasia has taken place in the tumors observed by us. On the other hand, we think that the same stimuli which caused the appearance of the sarcoma promoted the growth of the epidermal cells which were perfectly normal before the stimuli became effective. In fact, many things support this view. In the first place, the formation of the cancroid was apparent only in the subsutaneous transplantation of the tumor, being absent in intraperitoneal transplantations up to the seventh generation. Furthermore, in the fifth and the sixth generation of the tumor we could observe quite plainly the relation of the cancroid to the epidermal cells. The observation is especially interesting as in some later specimens we were able to see the influence of the tumor proliferating in the neighborhood of the epidermis, the cells of the latter showing a marked increase in number.

All these reasons make it quite probable that both the cancroid and the sarcoma which we observed in connection with the transplantation of an adenocarcinoma of a rat were caused by some irritative influence the nature of which we do not as yet know, originating from the proliferating cells of the primary newgrowth. With these observations we have before us the fact of the appearance of new tumors, not alone the continuation of the growth of a transplanted portion of another tumor. We are therefore in position to cause experimentally the development of a new formation, and, as Bashford very correctly says, this may give us the important opportunity to study the appearances and the growth of such a tumor from its very inception. Of course, the significance of such work for the questions involved in the study of cancer cannot now be estimated. One thing, however, must be kept in view: the principal reason for opposing the parasitic theory of the causation of cancer has been the claim that in the experimental studies of cancer not new tumors were produced in the animals but simply metastases of the original growth were artificially produced. Hauser, who is a determined opponent of the parasitic theory, has stated that the successful transplantation of tumors could be interpreted in support of the parasitic nature of the disease only when the tissues of the animal experimented upon could be made to undergo carcinomatous changes by the transplantation of the cancer cells into that animal. Such a phenomenon would happen in his estimation if the epithelial elements of the animal's skin showed carcinomatous proliferation after the subcutaneous inoculation of cancer cells into that animal. These conditions, which Orth also accepts as the criteria of a true infection, have in fact been fulfilled in the tumors observed by us. The skin of the animals experimented upon has been stimulated in such a fashion that carcinomatous overgrowth has taken place in its elements. Indeed, even if we leave out of consideration the development of the cancroid in our animals, the fact yet remains that the phenomenon observed in the tumors of mice by Ehrlich, Apolant, Loeb, Liepman, and Bashford, the stimulation of the connective tissue to sarcomatous change by the inoculation of cancer cells into an animal, has been seen by us in another animal, the rat.

The final significance of this phenomenon for the etiology of malignant tumors can be decided only in time and as a result of further observation and experiments.

RECURRENT AND ABDUCTOR PARALYSIS OF THE LARYNX; DIAGNOSIS AND TREATMENT.*

By W. E. CASSELBERRY, M.D.,

CHICAGO.

PROFESSOR-EMERITUS OF LARYNGOLOGY AND RHINOLOGY IN NORTHWESTERN UNIVERSITY MEDICAL SCHOOL; LARYNGOLOGIST TO ST. LUKE'S AND WESLEY HOSPITALS, ETC.

In the diagnosis of unilateral recurrent nerve paralysis which, when complete, results in the fixation of one vocal cord in the cadaveric position, the cracked, softly raucous voice, is suggestive rather than distinctive, but it is usually the one small symptom of an inversely grave condition which first causes the patient to seek advice. It is nature's distress signal, full of meaning to him who reads the code. The same is true of that partial stridor which may or may not usher in an unilateral abductor paralysis, in which the dilator muscle alone being powerless, the vocal cord is retained in a position closing over one-half of the lumen of the larynx. Either symptom demands a prompt resort to laryngoscopic inspection, but even then by reason of the fact that patients are liable to present themselves for the first time during a "cold" or other aggravating influence, confusing departures from the typical may be enountered, and one turns next to the really vital phase of the diagnosis, a search of the chest, neck, and central nervous system, for the cause and significance of the vocal paralysis. The tortuous course and complex composition of the recurrent nerves should be kept well in mind. Branching from the pneumogastric, the left one takes a turn under the arch of the aorta, *between it and the left bronchus,* upward to the larynx, while the one on the right passes under the subclavian artery, both being liable to compression by aneurysm, mediastinal, and cervical tumors, and, on the right, by disease at the apex of the lung or its pleura, which is crossed by the nerve. The similarity of lettering of the two words abduction and adduction is unfortunate, for, in addition to typographical errors, a conscious mental effort is necessary to avoid confusing one with the other, but as applied to the movements of the vocal cords, they are more exact in meaning than any other available terms. The opposing muscles, which effect the to and fro motion of the vocal cords, adduction for vocal vibration, abduction for breathing space, are innervated by different fibers, which merely travel in the same recurrent nerve trunk, either set of fibers alone to any degree, or both sets together, being subject to paralysis. Semon's law refers to the fact that the abductor fibres and muscles are the more vulnerable of the two, yielding first to an equal pressure on the trunk, and, in consequence, every complete paralysis of a vocal cord by pressure must have passed through a preliminary stage, however brief, of abductor paralysis alone.

Aneurysm Group.—The typical image of complete unilateral recurrent nerve paralysis illustrated in Fig. 1, is introduced as a standard from which to describe the diagnostic variations. It represents the larynx of a middle-aged salesman whose voice, he said, "failed all at once one day, while selling goods." Not only is the left vocal cord motionless in the cadaveric position, but it is relaxed, tends to bay outward, and its arytenoid, which is *not swollen,* has "fallen in," *i.e.* collapsed forward, which shortens the vocal cord and permits the cord to sink to a plane slightly below the level of its fellow. On phonation, the left arytenoid may give a twitch, but fails to straighten up or convey more than a mere tremor to the cord, while the opposite arytenoid and vocal cord, in an effort to compensate, overreach the center line, the sound arytenoid crossing a trifle usually in front or possibly behind the paralytic one, and the healthy cord coming nearly but not quite over to the paralyzed one. These are not insignificant details for their presence collectively, rather than the cadaveric position alone of the cord, insures the fact of a complete recurrent nerve paralysis. Its cause in this instance was equally evident. There was substernal pain and a radial pulsus differens, but no other symptom, excepting that in the fluoroscope, a small pulsating aneurysm of the arch of the aorta was visible. Five months later, while walking on the street, this patient fell dead with a gush of blood from the mouth: the aneurysm had burst, presumably into the left bronchus.

Life's duration in aneurysm, however, is seldom so brief. Dating from the early period of vocal paralysis, it has often surpassed my expectation; in one 10 years, in another 5, while others are now living at 2, 3, and 4½ years. The seemingly prolonged course, last mentioned, the patient being still active, is explained by the fact that it dates from the earliest demonstrable stage in the development of the aneurysm, as evidenced by the presence of unilateral abductor paralysis, which is the first definite effect of pressure on the recurrent laryngeal nerve. A sketch of the larynx made at that time (Fig. 2) represents the typical image of unilateral abductor paralysis and is intended to show not only the vocal cord motionless in the median or closed position, but also that the arytenoid has not yet "fallen in," hence the cord is but little depressed or shortened and not very much relaxed. Paralysis limited to abduction is not the only possible interpretation of the median position of a vocal cord, for one of the most deceptive of the variations from the typical image of *complete* recurrent paralysis is a fixation of the cord, not exactly in, but quite near to the median line instead of in the usual cadaveric position. Either form of paralysis is suggestive of an aneurysm, but with paralysis of the abductor fibers alone, indicating an earlier stage and more limited development of the aneurysm, a longer course is to be expected and an "arrest" or even a retrogression might not be impossible. Hence, in confirmation of the memorandum and sketch made of abductor paralysis in this case I will quote the additional notation inscribed, that "the vocal cord was not much relaxed and that the artyenoid, although standing a little forward, had not yet 'fallen in,'" a combination of conditions which I interpret to indicate an incomplete degree of paralysis of the recurrent nerve which, in connection with the median position of the cord, could be no other than an abductor paralysis. His *x*-ray print I find somewhat blurred by the effects of time, still it distinctly shows, representing the aortic arch, a broadened shadow which rises in the back above the normal limit of the fourth rib, with a bulge to the left which centers near the second rib and a smaller bulge to the right at the fourth intercostal space. A fluoroscopic examination also by Dr. John Kales and the author, was recorded at that time as follows: "A distinct, but small pulsating bulge in the descending part of the arch of the aorta could be plainly seen."

Since writing the above description with its deductions relative to the 4½ years' duration of an aortic aneurysm, this patient, known to have re-

*Read as part of a symposium before the American Laryngological Association, May 11, 1908.

mained vigorous so long as to suggest a shade of doubt in the diagnosis, has returned, thus enabling me to complete the evidence to date, with respect both to the laryngeal paralysis, of which he is conscious only when further disabled by a "cold," as at present, and to the aneurysm which does not even

Fig. 1.—The typical image of complete left recurrent paralysis. The vocal cord, in the cadaveric position, appears relaxed, narrowed, shortened, and depressed; the arytenoid "fallen in," not swollen.

yet cause any subjective symptoms other than the vocal cord paralysis. Reexamination confirms all of the original findings, with natural progression. The position of the left vocal cord has advanced from the typical abductor or first position, partly but not wholly, into that of complete recurrent paralysis. It now exemplifies that variation from the typical image of complete recurrent paralysis described as: "a fixation of the cord not exactly in, but quite near to the median line instead of in the usual cadaveric position." Intensified tubular breathing, the physical sign emphasized as coming next after vocal paralysis, is now heard in the back at the left, above the angle of the scapula and, as might be expected with compression of a bronchus, the vocal resonance and fremitus are diminished at the same point. A blurred, widely transmitted first sound stands for the aneurysmal bruit and the right subclavian impulse is in excess of the natural. The fluoroscope and *x*-ray plate show a clearly defined sacculated aneurysm together with a diffused distension of the rest of the aortic arch.

It requires but a slight expansion of the aorta at a given spot to compress the left recurrent nerve, hence the frequency of even a complete recurrent paralysis at comparatively an early period, when perchance one may search in vain for any other classical sign of the aneurysm which in fact can still be so small that even a radiograph will leave a doubt behind, as in Fig. 3. Here there was neither bruit, thrill, tracheal tug nor protrusion, yet there was paralysis of the left vocal cord, and there was, moreover, a noteworthy accessory physical sign, *i.e.* an exaggerated bronchial breathing transmitted to the back, a symptom which, coming early, *pari passu* with vocal paralysis, should be of special diagnostic value to the laryngologist, for an aneurysm which compresses this nerve must at its very next step compress the left bronchus. An appreciable diminution in the vesicular expansion comes only later.

It has been noted that in the typical image of complete paralysis, the "fallen in" arytenoid is not swollen; but exceptionally, as a departure from the typical image, a coexisting swelling of the arytenoid is seen, which is liable to disguise the paralytic aspect and to cause the condition to simulate a cricoarytenoid ankylosis with fixation of the cord. Figure 4 represents this important variation. When first observed, the right cord was stationary, but in a doubtful position, the arytenoid and subglottic tissue was swollen and the left cord also was sluggish in movement. It was only after some weeks of detergent local treatment that the cadaveric position of the right cord could be accurately determined, the left cord meanwhile having definitely weakened into the first position, that of abductor paralysis, which, in conjunction with the other lesions, sufficed to cause an alarming respiratory stridor on exertion or on "taking cold." Aneurysm was now evidenced by other signs, and its existence was later verified in Berlin by Dr. Krause, who, in explanation of the swollen arytenoid, wrote: "The small tumefaction of the arytenoid is a little bit unclear, but may be caused by a prolapsus of the cartilage." Hooper, also once drew our attention to certain "anomalous muscular fasciculi* innervated from other sources, which, when present in conjunction with recurrent paralysis, would serve to pull the arytenoid forcibly forward." The possibility, thus, of a partial dislocation of the arytenoid amounting to a prolapse instead of merely a collapse, is a striking point in diagnosis to be remembered, especially with reference to the differentiation of paralysis from ankylosis, which is rendered thereby all the more difficult.

The bilateral inflammatory form of paresis of the internal tensors with its familiar ellipse, is in no danger of being mistaken for recurrent nerve paralysis, but I have twice observed in clergymen an unilateral internal and external tensor paralysis, induced by vocal strain, but of so severe a grade as to simulate and perhaps in a way to partake of a recurrent nerve paralysis. Assuming for it a neuromuscular rather than a strictly myopathic basis, it is the nearest approach to a direct impairment of the nerve endings which my series affords. The level of the cord is lowered, its range of movement to and fro lessened, and the arytenoid disposed to collapse, but it is distinguishable by a predominance of the flaccid tensor element, absence of lead, alcohol, or other toxemia, absence of any cause of pressure, and it finally recovers by rest to the voice.

Out of a total of forty cases upon which this

study is based, the left recurrent nerve was paralyzed by an aneurysm in eight and the right recurrent in six, including in both numbers those in whom the opposite cord was likewise but less affected. Concerning the treatment, in only a few of the aneurysm group was local medication indi-

cated, and then not for the paralysis itself, but rather to aid in strengthening the voice or in diminishing the stridor by controlling the inflammatory complications. Moderation in voice use is enjoined on all and soon has its reward in distinctly improved tones, the voice, in time, through com-

Fig. 3.—Aneurysm, so small that the radiograph alone would have left it doubtful. Complete paralysis of the left vocal cord and exaggerated bronchial breathing present

pensation, often becoming fairly good for conversational use. The prognosis of aneurysm, in general, is not so absolutely bad, and discovered at an early stage it should be better. Syphilitic arteritis in other situations—for example, in the brain—elicits and yields to a vigorous specific treatment; why not so in an early stage of aortic arteritis?

Pleuritis Group.—Four additional paralyses of the right cord compose the pleuritis group. All were tuberculous and in none could any other cause be assigned than an assumed circumscribed pleuritis. In one of them, whatever might have been the exact cause of a recent and complete unilateral right recurrent paralysis, which showed a typical image, a perfect restoration of power to the cord was gradually attained contemporaneously with a treatment by fresh air and rest for the incipient tuberculosis. Our means of certifying a diagnosis in this group are as yet sparse. The *x*-ray should be of service for the purpose of excluding or establishing the presence of enlarged mediastinal lymphatic glands on the left side, which in tuberculous subjects constitute a possible cause of pressure on the recurrent nerves, but on the right side enlarged glands so located would scarcely be beyond the reach of deep palpation. However, a radiograph was taken of this particular patient, who recovered, and no abnormality was shown. Her reaction to the tuberculin test was positive.

Tumor Group.—Another departure from the typical image of complete paralysis is presented in Fig. 5, in that the ventricular band is hypertrophied and almost covers over the paralyzed cord, nature having gradually put forward this false cord in compensation; it vibrates with the sound cord and produces a fair voice. It is selected from my next group of eight cases in each of which a tumor was the cause, and in all but two of which, unlike in the aneurysm group, the vocal disability appeared only as a late and gradual development. In this patient a primary malignant growth had been removed from the chest wall three years previously, a fact which he considered so irrelevant to vocal trouble that he deliberately falsified when I asked about the scar, saying he had been struck by a shell during the war. A grimly humorous episode served, in the interests of science, to complete my record of this case, for, the autopsy having been held in my absence, the widow, who, it appears, had fervently disapproved of his falsehood about the scar, entered one day and dramatically deposited a large package before me on the desk, stating exultingly: "There, that's what he had." It proved to be a sarcomatous tumor from the mediastinum.

In this group, also, I find another observation, that late in the course of a carcinoma of the esophagus, an irritable cough and weak voice having appeared within a fortnight, the left cord was found motionless, near to, but not exactly at the line of abductor paralysis and that the arytenoid had not "fallen in." Evidently the paralysis was progressing gradually and a remnant of innervation remained.

Esophagoscopy has been helpful, although usually, by the time a vocal paralysis supervenes in carcinoma of the esophagus, the diagnosis is plain. I was once temporarily misled with respect to the larynx by a condition which suggested a dawning vocal paralysis in consequence of esophageal neoplasm. There was post-prandial eructation of what the patient called "a lot of phlegm," but which in reality was a fermented mixture of mucus and food which irritated the arytenoids and enfeebled the voice, but obscured the image. The *x*-ray disclosed a bulge and showed the arrested bougie within it (Figure 6). The esophagoscope, passed under general anesthesia, was arrested at this same point, where an easily bleeding mammillated mucosa was plainly seen, the exact nature of which, however, it was impossible to interpret. As a palliative treatment in this particular case, which proved *not* to be one of paralysis, the expedient of assuming an inverted recumbent position after each meal, which by gravity emptied the pouch, has afforded a gratifying relief to the throat symptoms, which two years ago were quite distressing. Meanwhile, the obstruction in the esophagus, whatever its nature, remains still in *statu quo*. Having the appearance of a neoplasm, it is of interest in this connection because it is differentiated from aneurysm by the fact that it does not pulsate as observed in the fluoroscope, and because it is in line with the dictum that vocal paralysis, unlike in aneurysm, is not an early symptom of neoplasm of the esophagus, unless the latter is located high up.

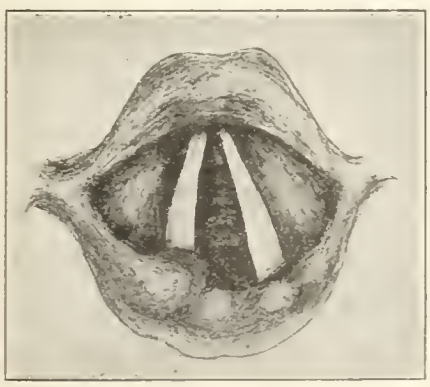

Fig. 4.—A variation from the typical image of recurrent paralysis. The arytenoid is swollen.

We recognize in the so-called "lazy cord" a symptom of carcinoma of the larynx, but I think it is little known that total immobility of a cord in the cadaveric position may be the first visible evidence of carcinoma of the larynx. Through a surprise of this sort at autopsy, I am able to duplicate

the single observation of it which Semon[2] records in these words: "*Einmal* habe ich eine bosartige Kehlkopfneubildung in Form der Unbeweglichkeit einer Stimmlippe in Cadaverstellung beginnen sehen."

The other exception to a late development in the

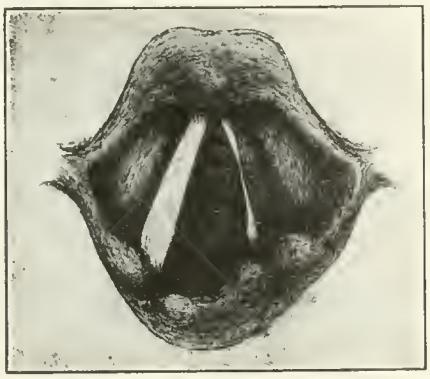

FIG. 5.—A variation from the typical image of recurrent paralysis The ventricular band is enlarged.

tumor group occurred with a high carcinoma of the esophagus and involved both cords, the left a cadaveric, the right an abductor paralysis. The end was then approaching, but aphonia two years before had been the very first symptom, the reason being that high up the recurrent nerves lie so close to the esophagus that not only one but both nerves are liable to be affected by pressure or to be incorporated in the carcinoma almost at the start.

Goiter was responsible but once for a complete paralysis of a vocal cord. It was a small, firm enlargement of the left lobe, which was treated by surgical removal, but the nerve had already atrophied. In goiter, when the voice begins to weaken, the cords should receive the closest scrutiny, for surely the first definite evidence of paralysis would be an additional incentive to surgical interference. This principle pertains equally to other cervical tumors and to enlarged lymphatic glands. Its value was brilliantly evidenced in one of this group by a complete restoration of voice which followed the excision of three tuberculous glands in a school teacher, whose left vocal cord previously had been motionless in the cadaveric position.

The large variety of conditions capable of inducing recurrent nerve paralysis is emphasized by an error in diagnosis of which I became apprised only when tracing the patients for the purpose of this report. The image of complete paralysis of the left cord was typical and without tumefaction inside the throat. A swelling in the neck at the site of the thyroid gland was naturally mistaken for a goiter, the subject being a girl of 18 years. Goiter was accepted as the cause of the paralysis and its surgical removal recommended, but not done. Signs of tuberculosis at the right pulmonary apex seemed to explain her anemic or cachectic appearance. The supposed goiter turned out to be a malignant neoplasm, which terminated as usual about a year later.

Centric Bulbar Abductor Group.—Like other respiratory muscles, the abductors of the vocal cords (dilators), being impelled by reflex action, have their main centers in the medulla oblongata (bulbus), so near together that naturally the symmetrical double abductor paralyses predominate in my bulbar group. The mere fact of *symmetry* in persistent abductor paralysis is indicative of a bulbar lesion. When uncomplicated, the appearance in the mirror is pathognomonic. The flaccid cords which will not separate, their edges flapping up and down like a sail in the wind, are unmistakable. The question of a possible overpowering spasm of the opposing adductor muscles did not need consideration in any of this class, although it may arise especially in connection with the intermittent stridor of an incipient stage of abductor paralysis and also in the unilateral type. The differentiation from ankylosis may require the same degree of critical observation as recurrent nerve paralysis. A paralytic immobility is liable to lead into a sort of ankylosis or stiffness of the joints, and, moreover, there is at least one form of arytenoid arthritis, previously described by me under the name of "Arthritis deformans of the Larynx,"[3] which causes a symmetrical ankylosis without much tumefaction.

An energetic course of mercurial and iodide medication is indicated whenever the centric degeneration is connected with tabes or with any other suspicion, however remote, of syphilis, for exceptionally one finds recorded a practical recovery. Eight cases of abductor paralysis compose this bulbar group, four of them being of the persistent symmetrical double type. Unfortunately, in all of these four the varied treatments did naught but eventuate in tracheotomy which, although far from an ideal remedy, remains still the best life-saving device. For eight years one of them had been wearing a tracheal tube of the sort which is fitted with a ball socket valve which enabled him not only to inspire with freedom but to talk with ease, for the obstruction by abductor paralysis is inspiratory only, the downward air pressure forcing the vocal cords even closer together, while the outward air pressure balloons them slightly apart. Thus, by a skilfully modulated use of the expiratory current which served instantly to close the tubal valve, forcing the air through the chink of the glottis, he could uninterruptedly intone and articulate sentences of considerable length. Neither this patient, nor another, who had been dependent for his life during several years upon a simple tube which to effect conversation required stoppage by the usual conspicuous method of holding the

FIG. 6.—Esophageal neoplasm, with arrested metal bougie. Differentiated from aneurysm by absence of pulsation when observed in the fluoroscope.

finger at its opening in the neck, would, on account of the risk of speech involved, consider any effort to widen the glottis to the small extent which would be adequate for ordinary breathing, either by means of an excision of one cord or by the proposed method of causing it to assume the cadaveric posi-

tion by a deliberate section of the recurrent nerve. The latter method, supplemented perhaps by mobilization of the joint if stiffened, would seem worthy of a trial considering that the wearing of a tracheal tube is in itself a menace to life. Neither of them suffered from tabes but both gave a history of syphilis.

Not only the parasyphilitic degenerations but also the degeneration incidental to advanced age may happen to strike these minute centers in the medulla. It was the only apparent lesion, without other cause, in a woman of 75 years. With her, a treatment by emollients and mild vascular astringents sufficed, under careful observation, to defer for some months the ultimate tracheotomy; and the same line of treatment in conjunction with antisyphilitic remedies was finally successful in another one of this group, but of a different type, the condition being a partial and unsymmetrical abductor paralysis in which the stridor became serious only during periods of acute exacerbation by "a cold."

The remaining representation in the bulbar group is of that combination which anatomically is far from clear, now that the spinal accessory nerve is not considered contributory to the recurrent nerve, in that the abductor paralysis being unilateral and devoid of symptoms was discovered incidentally, as the complaints had reference to difficulty in swallowing and articulating, in consequence of paralysis of the palatal, pharyngeal, and lingual muscles, together with atrophy, in one instance, of the trapezeus and sternocleidomastoid muscles. One, the victim of a generalized arteriosclerosis without syphilis, was not responsive to any form of treatment and succumbed from inanition, while another, a syphilitic, was benefited by energetic specific medication to the extent of regaining an ability to swallow liquids without a nasal reflux and to articulate with fair distinctness.

Centric Cortical Group.—Owing to the bilateral laryngeal action which ensues from an unilateral cortical stimulus, it is supposed that paralysis of one vocal cord from a lesion of the opposite side of the brain, really does not occur, and that some fallacy has underlain the few apparent cases which have been recorded.[4] Delavan[5] reports, in convincing detail, one case previously published as cortical, in which at autopsy was found a conjoined bulbar disease; but probably the fallacy also lies in mistaking the "stroke" of a syphilitic endarteritis for that of true hemorrhagic apoplexy. Laryngeal paresis can, of course, ensue from organic cortical lesions which affect the brain centers of both sides or interrupt the nerve fibers in transit from both sides, as in syphilitic degenerations or arteriosclerosis: and the six cases which compose my centric cortical group may have been either of this nature or else similar to Delavan's case. In three of them the vocal paralysis occurred in connection with attacks of so-called apoplexy, but as they were men under 50 years of age, with venereal histories, did not lose consciousness at the time of the "stroke" and had recovered in some measure, the attacks doubtless were due not to unilateral hemorrhage but to syphilitic cerebral arteriothrombosis which is often unequally bilateral. In none was a typical image of paralysis of any particular group of laryngeal muscles presented, although the left cord in one, was nearly, but not quite, motionless in the cadaveric position, the condition in two being an incomplete bilateral paresis which predominated in the larynx on the side of the paretic arm and leg, as evidenced by a feeble closure of the flaccid cords in a slanting position. Either an enfeeblement of the pharyngeal muscles or impairment of articulation or mild aphasia was associated with the laryngeal paresis in one or another of this subgroup. One of them has remained under observation, receiving antisyphilitic treatment during a period of seven years, and is now well.

The others of this group were persons somewhat advanced in years who presented symptoms, in general, of cerebral degeneration, the paresis of the vocal cords being the cause, only in part, of the difficulty in speaking. Although hoarseness and weakness of the voice were particular complaints, the laryngeal image was not typical and represented an unequal paresis of both cords rather than a complete paralysis of either cord. The local treatment was mildly palliative, only, but proved far from useless. The detergents and emollients applied by simple methods served to lessen the friction of vocalization and thus represented to the aged sufferers the difference between misery and contentment.

MEDICAL TREATMENT OF APPENDICITIS.*

By G. R. CRUIKSHANK, M.D.,
WINDSOR, ONT.

The successful treatment of inflammation of the bowels by removing the appendix is one of the great achievements of the nineteenth century, yet this very success brought with it the expected evil, too much operation for abdominal pain.

It must be acknowledged that there are some cases that can be well treated only by operation and more that are best treated this way, but physicians cannot agree with Deaver, that "the only true conservatism in appendicitis lies in recourse to the aseptic scalpel," or with Osler that, "there is no medical treatment for appendicitis."

The purpose of this paper is to elicit discussion and only those points will be presented upon which there is difference of opinion.

Where there is much operating there is a high death rate. It is acknowledged that England and especially Germany are behind the times in operating for appendicitis. Osler shows that the death rate from this disease per million is: in New York, 129; in Chicago, 140; in England about 45. During ten years in the Boston City Hospital 2.2 per cent. died; in Vienna, 0.3; in Munich, 0.5. That is four times as many in New York as in Munich, and seven times as many as in Vienna. These figures were used to show the relative prevalence of the disease, but is it not remarkable that the higher death rate should occur where appendicalgia operations are the fashion? The same author says that the mortality has been increasing in England in spite of earlier and better surgery!

It may have been just such a situation as this that caused Ochsner to say: "The death rate after appendicitis operations in the hands of incompetent surgeons is absolutely frightful." It seems we must concede that where there is more operating there is a higher death rate and look for less operating or

*Read at a meeting of the Ontario Medical Association, May 28, 1908.

greater competence. How are we to know who are competent?

There is much needless operating. Many surgeons who open into the abdomen for other complaints remove the appendix whether it is apparently diseased or not. Petersen in 285 cases found lesions in the appendix in 50 per cent., Hunter Robb in 370 cases found lesions in 267. J. G. Clark in 120 laparotomies found only 25 appendices normal. It may be presumed that much of the pathological work was done in the laboratories of Ann Arbor and the Johns Hopkins Hospital. Kelly thinks 60 per cent. of these tissue changes are of pathological origin. Ochsner says a large proportion of all human beings suffer at some time from appendicitis. If this be true and if the best treatment for appendicitis is the scalpel then at least 25,000,000 on this continent need an operation at once.

Physiologists tell us that these changes are not pathological, but due to involution. In 25 per cent. of the human race epithelium and glands perish, lymph nodules disappear, and the tunica propria is transformed into an axial connective tissue strand. These views are commonly accepted to-day. If the physiologists are right the surgeons are wrong, and their statistics unreliable, besides they remove enormous numbers of normal appendices, 25 per cent. at least free even from physiological change.

The amputation of the appendix would not be a matter of much concern if it were a developmental vestige of no use whatever, but an actual menace to its possessor. I have not seen statistics anywhere as to the longevity of those whose appendices have been removed, but those whom I have met have not always been distinguished for robust health. It is not certain that the appendix is a developmental vestige of no use whatever. Berry has advanced good reasons for considering it rather the opposite, a higher grade of lymphoid development and accumulation of these elements. The colon is the seat of lymphoid tissue. In the lower animals it is scattered over the gut, in the higher it becomes collected, and in man mainly concentrated in the appendix.

McEwan, who studied this organ through a wound in the side, noticed that the glairy secretion of the appendix was alkaline and mixed with the acid chyme of the ilium, neutralizing it upon its entrance into the colon. He noticed also that the secretion was influenced by the mental states of the patient, in a manner comparable to the saliva, and concluded that the secretion of the appendix is a valuable aid to the completion of digestion.

Prior to 1888, the birth year of appendicectomy, Fagg's System of Medicine says: "Not one death from typhlitis had occurred in Guy's Hospital during five years except in those who were moribund on entrance." In St. Thomas' Hospital about 70 per cent. are allowed to recover without operation.

I am sorry I have not a record of all the cases of appendicalgia I have treated during twenty years, but during this time I was pretty busy in a small city where appendicitis was the fashion and only one death occurred and that was of a patient whom I passed to a surgeon four hours after I first saw the case. During this twenty years only ten patients were operated upon.

A large proportion do not have a recurrence and those who do, usually have mild attacks if they take care of themselves. I have always maintained this stand and it is pleasing to note that this is now generally acknowledged. Surgeons take a gloomy view of this matter because they see only the severe cases.

The contents of the colon form a culture for an enormous number of pyogenic germs, harmless so long as the mucous membrane is entire and the germicidal power of the serum is sufficient. Anything that injures the mucous membrane, such as trauma or distention, or that interferes with the circulation, such as kinking or thrombosis, especially if the resisting power of the blood is weakened, may cause an attack.

The differential diagnosis is not easy. The disease may be confounded with lesions of the gall-bladder or kidney, or with tuboovarian diseases. Every intestinal pain does not come from the appendix and we must consider fecal impaction, neoplasms, nerve and cord affections, injuries of the body wall. I saw a distinguished operator remove ten appendices in one day, one contained pus, one was club-shaped, one was in a case of typhoid fever, and seven apparently were normal.

A not uncommon cause of error is hysteria. An imaginary appendicitis is quite common in both sexes and this condition is fostered by unwarranted assurances of disaster by surgeons. Five years ago a young woman was warned by a prominent operator that if she did not submit to an operation she would have a recurrence and likely death. She has had no recurrence to date. That hysteria is not confined to patients is clearly illustrated by the history of appendicectomy.

Treatment.—In most cases the lesions begin in the mucous membrane as a bacterial infection and inflammation which may proceed to ulceration, abscess, perforation, or gangrene. Resolution may occur before the formation of an abscess and even with abscess, perforation, or gangrene there are undoubted instances of recovery.

The original infection is usually in the mucous membrane and exists before the patient is aware of his illness. There may be very little discomfort or pain but in most cases a careful inquiry will disclose a prodromal period in which the patient has suffered from malaise due to the toxemia. This is a stage of the disease overlooked by textbooks which speak of the onset of the disease at the time of the attack of pain.

Pain does not usually commence until the deeper structures of the wall are involved and consequently may not occur at all. The recognition of this prodromal period is important for reasons that I shall refer to again in speaking of purgatives. Some twenty-one different germs have been isolated in these lesions, but Dudgeon and Sargeant have shown that usually the first of the bacteria to migrate are the *Staphylococcus albus* which stimulates phagocytosis and causes the peritoneum to protect itself with a fibrinous exudate that walls off the infected area. Marked pain does not usually occur until this stage, when nature makes any movement of the bowels painful in an endeavor to save its protecting wall. Meanwhile if recovery ensues the phagocytes and antitoxic elements destroy the bacteria and permit the healing of lesions in the usual manner. Obviously our treatment must be directed towards securing rest for the inflamed part and aiding this phagocytic action.

To secure rest, we must endeavor to arrest peristaltic action, and since the mental state causes a flow of appendicular secretion, to avoid even a suggestion of food. As soon as the condition is suspected the patient is sent to bed and nothing but very little water is permitted until the symptoms have subsided. It is not unusual to keep a patient on water for ten days. During this time I do not favor even much rectal alimentation for fear of

stimulating peristalsis. The return to food must be very gradual. It is remarkable how little hunger patients really have. If questioned closely, their desire for food is found to be a mental process, instinctively they do not want it. I have known children at the hungry ages of five and six to have no desire for food for a week. I wonder if our habits of eating when not hungry have not much to do with causing this disease.

As to purgation, most authorities favor at least one initial purge, many favor purgation throughout. I do not believe a purge at any stage is advisable. If it is permissible at all it must be during the prodromal stage before the onset of pain, with the hope of lessening intestinal autointoxication. If the rectum is loaded a saline enema may be in order, once only.

If the intestinal inflammation is slight the purgative will do little harm, and if little harm results the case is certainly a mild one, and this suggests a possible use for a purgative, viz., as a means of diagnosis. A case that is so mild as not to be markedly aggravated by a purgative is so mild that an operation is not called for. Defecation has no more to do with recovery than a thermometer with the weather. I commence the treatment by assuring the patient that I do not care if the bowels do not move for a week. I recall a case that was presented at a hospital for operation in a moribund condition. The attending physician stated that he had used every means to produce an evacuation, even croton oil, but in vain. The patient suffered from complete paralysis of the bowels with extreme distention. Of course he died. I believe that purgation has caused more deaths than operations. The advocates of purgation reason that the feces are a mass of virulent germs and should be gotten rid of. In reply to this it may be stated that at operations the cecum is never loaded with feces; it is impossible to sterilize the mucous membrane with a purge, and the bacteria in the lumen are of little importance as compared with those in the wall.

Morphine is objected to because it masks symptoms. But what objection can there be to this? If the pain is severe enough to call for morphine it is time to decide whether to operate or not.

Nothing can be gained by a day's delay. Now is the time to decide. Operate at once or not during the attack. If the case is treated during the prodromal stage severe pain will not likely occur. If it is first seen shortly after the onset of severe and sudden pain, one should operate. If the pain sets in suddenly, even if it is not severe, an exploratory incision is in order. If there is any doubt as to these points, the life at least of the patient will be safe with nonoperative treatment. Morphine by relieving spasm may permit the escape of a fecolith. In any case by securing rest it will do much more good than any harm it is said to do by inhibiting leucocytosis. After the first few hours by the aid of an ice-bag morphine will not be required to relieve pain.

There is no specific for this disease, nor is there for typhoid fever, but the art of the physician where there is no specific is of an inestimable value in these and many other conditions. If there is no medical treatment for appendicitis then there is no medical treatment for typhoid fever.

To operate or not to operate, is the question, as well as when to operate. It is a common practice to use nonoperative means until there is evidence of an abscess, then to operate. This I think is unwise and I believe it to be the chief occasion of the deaths. If we wait till the leucocyte count indicates that pus will form we have waited too long. The heaven gifted artist can operate with impunity any time, but the average surgeon should delay till pus is walled off, has lost some of its virulence, and the patient has developed some immunity.

The operator is afraid the abscess may burst into the peritoneal cavity. As to this Ochsner says, "the last cause for diffused peritonitis results from the bursting of the circumscribed abscess. I believe this is practically always avoidable by limiting the motion of the small intestine." This is the conclusion of all conservative physicians. By waiting the death rate has been reduced 11 per cent.

I have seen a most desperate case that one of the most eminent surgeons in America declined to operate upon recover with nonoperative treatment.

L. M., daughter of a physician, was seized with violent pains, high fever, hard pulse on December 1. Her mother was so much averse to operation that it was decided to use nonoperative means. She was placed in bed, hypodermics of morphine were given, an ice-bag was applied, and water only was allowed. Temperature 99° on December 5. On the day after eating an orange the pain recurred, the temperature rose to 104°, a tumor was distinctly outlined; decided leucocytosis was present. It was decided to wait. The ice-bag was continued, the patient was placed in Fowler's position, and no food was allowed; the temperature was normal by the 11th. Tumor was still present but gradually disappeared. The child is now perfectly well, and the operation is indefinitely postponed. If an attack occurs again it will be milder, and if it recurs the appendix will be removed as a matter of convenience.

This case should have been operated upon at once, but it illustrates nonoperative recovery of a pus case. This has been my experience often. It is not necessary to operate because of the presence of pus, but it is much better and safer to do so subsequently. Every case of violent and sudden pain calls for an immediate exploratory incision, as it may indicate perforation.

A case of neurasthenia or hysteria with intestinal indications calls for exploratory incision. The presence of a fecolith should not cause the sacrifice of the appendix. Chronic or relapsing cases should be operated upon as a matter of convenience and not as a matter of life and death.

Conclusions.—A few cases of appendicitis can be treated successfully by operation only; others are best treated by this means, but the great majority of cases are amenable to nonoperative treatment, no food or purgation, rest, judicious use of morphine, ice-bag or hot applications, and Fowler's position. Enormous numbers of healthy appendices are removed. An operation should not be done during the acute stage.

"The mortality from appendicitis operations in the hands of incompetent surgeons is absolutely frightful."

If there is doubt whether to operate or not,—don't.

Every expert operator is not a surgeon, the former possesses merely dexterity and the latter wisdom. The former works for various reasons and the latter for the comfort and longevity of his patient.

The Ontario Board of Health should establish a Pathological Laboratory to which every operator should send all tissues removed for a private report so that he at least may know if he has removed normal tissue.

THE PHYSIOLOGY AND PATHOLOGY OF THE EMOTIONS; THE PHYSICAL BASES OF MENTAL ETIOLOGY.

By HOMER WAKEFIELD, M.D.,

NEW YORK.

Medical literature is filled with reports of clinical observations of disease causation from mental and emotional sources, but, notwithstanding that the best clinicians and most acute and reliable observers have been numbered among these writers, however singular it may seem, their statements have been contradicted, their observations have been disputed, and their veracity has been questioned. Why? Because the less careful observer and the less competent thinker could not reason out the relation existing between the mental and emotional states and, supposedly, more physical functions of the body.

There are three principal classes of theorists in regard to the so-called relation of the soul and the body, or rather the mind and the body: First, the class who believe the soul is the spiritual entity which presides over and operates through the medium of the body. This doctrine is taught by all religious sects in connection with the doctrine of the immortality of the soul, and receives its extreme significance in Christian Science, in which nothing tangible is recognized except the soul, the divine ego, which is all in all with the deity, and nothing further exists except as the materialization of thought; thus, in the above class, we have in the first subdivision a body simply as the vehicle or medium of the mind, and in the second subdivision we have a body and environment in general which exists and undergoes modifications as a mental function, so to speak.

The second class represents that class that can conceive of no possible relation between the mind and the body, and regards as absurd the interrelations of physical as well as mental influences, as little less than idiotic.

The third class, the cause of which this paper is to espouse, conceives of the mind as the functional product of the brain, which is part of the body, and dependent for its sustenance upon the general body vigor. Even the will, which apparently dominates the voluntary functions, is subject to the perversions of disease, and is more or less suspended or in abeyance during emotional states, as we shall observe later on.

If the physiological and pathological observer is to interpret his observations correctly, he must at once discard the first two doctrines and pin his adherence to the third. We must admit the interrelations of the mind and the body, and either admit a mental or spiritual domination or creation of the mortal body, or recognize the physical bases of mental influences upon the body, originating in environmental and extrinsic conditions, operating through the senses and the balanced cooperation of the brain cells, representing memories of the life experiences of the human or subhuman animal in reaction with the current sense perceptions.

Theological dogmas are commonly inconsistent with physiological and pathological fact, and, unfortunately for medicine, policy or tact has led too many to either evade the direct discussion of the subject or to color the truths so as to avoid inconsistencies or direct incompatibilities. Physiology and pathology have been great sufferers from this fault, but the time has come when the truth must be spoken, whosesoever toes are stepped on. Someone must have the courage of his convictions to be the first to direct the attention to this fact, and it might as well be the writer.

I might mention that the churches themselves will soon be called upon to choose between the same incompatibilities. Some have already found it most consistent with their views to take up faith cure healing. Those who choose not to, may find it to their liking to accept the physical bases of mental influence upon the body, as many churchmen and many of the most eminent clergymen have already accepted the doctrine of evolution.

When the correct physiological and pathological principles of mental and physical interrelations are better recognized and understood, there will be evolved a revised code, ethical and penal, for the government of the interrelations of man. Mourning customs, which prolong and revive the agonies of grief and sorrow, will be dispensed with, and happiness, good cheer, and wholesome pleasures will be cultivated. Laws will be enacted to punish the offender against the senses as against those offending against the flesh. Unnecessary noises, aggravations, hectoring, scolding, tantalizing, and other offenses that cause worry, anxiety, loss of sleep, etc., will be punished by the index of the physical suffering which will be recognized as so produced. Unwarranted damage suits, blackmail, robberies, buncoing people out of their property on the stock exchange and otherwise, will get the added penalty for the physical suffering inflicted upon the victim. Fright and fear will be among the physical injuries punishable.

Medical literature is full of recorded observations of chorea, epilepsy, shock and collapse, nausea, vomiting, jaundice, and other ailments occurring as products of fright and fear; even death has resulted. Melancholia, mania, chronic nephritis, cancer, and diabetes from grief, worry, anxiety, dread, and disappointments are not uncommon. One could fill several volumes with detailed clinical records of such cases, easily collated.

The question arises, What is the physical basis of emotional pathology? What structural changes have been found to result from the emotional states that have escaped earlier observers?

Modern biology has proved that the reaction manifestations of protoplasm to all of the five forms of energy, namely, mechanical, chemical, thermal, photo, and electrical, are practically the same. If on irritates any protoplasm, from a rhizopod to a muscle of a higher animal, with any one of these agencies, it first exhibits a state of hyperesthesia and an imperfect contraction, exhibiting tension or twitching. If the irritation is increased, a well defined contraction is observed; continuing on we observe a tetanic contraction is developed; further still and the breaking integrity of the contraction is observed; and if further extended, a complete exhaustion relaxation is attained to. This, I have dubbed *The Biologic Series*, because of its being common to the plasm reaction of the entire zoologic scale.

This series exhibits other attributes besides those above described, and it may be said that a muscle may be irritated to go through the same series of phases when the stimulus is conveyed to it through a nerve. If the muscle is connected with its nervous centers in a living person, it is found that twitching but no pain accompanies the first stage. The second stage is characterized by a tensional or "nervous" sensation. The third or tetanic stage is characterized by pain, and the acuteness of the pain depends upon the size of the muscle as well as the degree of the tightness of the contraction. The cramps of the

thigh muscles are less painful than those of the calf, while the small facial muscles involved in a neuralgia, are the most painful in the body; and the pain is most acute. As the incomplete contraction involves twitching, the breaking integrity of the contraction involves clonic convulsive movements, and as the fore part of the responsive phenomena extending up to the maximum of the reaction vitality, ranges from the disagreeable hyperesthesia, involving hypersensitiveness with its exaggerated responsive phenomena, to actual pain. Then follows an exhaustion relaxation of the tetanic contraction, which ranges from an irritable weakness to actual anesthesia.

Epileptics pass, in their body aggregates, through this series; gradually attaining to tetanic, then to clonic convulsions, ending in flaccid relaxation and exhaustion. Some diseases exhibit this grades series in localized areas. The numbness that follows excessive fatigue and then anesthesia (the God given relief) that comes to the relief of great suffering, are examples of this law.

If a muscle or any segregated area of the body be deprived of oxidation (and I have presented evidence in another paper to prove that all the irritations, above mentioned, act by disturbing the oxygen equilibrium of the tissues), the reaction is the same as when irritated. All protoplasm proceeds on through the biologic series as a reaction to a sufficiently continuous deprivation from oxygen, or its oxidation, might be caused by depriving it of a sufficiency of its normal catalysis or its alkalimity. Suffocation will cause the body aggregate to pass through a modification of the biologic series: hanging, as capital punishment; carbonic oxide poisoning, and other agencies, when not too rapidly accomplished.

This leads us to the connecting web between the above described effects of the emotions upon the respiratory function, and gives us the explanation how the serious disturbances of our respiration, our prime means of oxygenation, prove so serious to our bodies.

Now, another feature of the biologic series is in this line. I refer to the density of the protoplasm. Beginning with a normal tissue, we find it has a high density or specific gravity, but, as we excite it past the physiological limit, beyond its functional capacity for response, we observe that it becomes by gradation progressively rarified; it is losing its surface tension and osmotic pressure, and if in the presence of water, it absorbs it. When it proceeds to a certain degree, it loses its impermeability to the blood: first, to its fluid, and secondly, to its more solid constituents, and these elements are extravasated out into and are absorbed by the tissues, which thus become correspondingly more succulent or liquefied. The significance of all this is that the degree of rarefaction attained is an index of the degree of pathogenesis developed from any cause.

Unfortunately for medicine, pathologists have heretofore studied morbid changes in tissues in regard to their structural modifications: *i.e.*, such as atrophy of parenchymatous tissue, or thickening of connective tissue, a phase of retrograde metamorphosis beyond that representing simple softening Mental and emotional factors may seldom enough produce actual structural changes as pathological anatomists use the term, but rarefaction, with a significance, serious enough, is easily determined as a sequence of emotional states.

Hack Tuke graphically defines by analogy and relationship fear, grief, anger, and hate as follows: "Fear, and its acute or sudden form of fright, an intenser form of terror or horror, with the minor ones of faint-heartedness, anxiety, and care, though the last may be regarded as gaining in chronicity what it loses in intensity. When epidemic, fear assumes the panic form. Allied to suspicion."

"Grief, or sorrow, is, in its various stages and degrees, synonymous with sadness, affliction, distress, discontent, melancholy."

"Anger and its aggravated phases of rage, fury, wrath, or what is commonly understood as passion."

"Hate, the ignoble and more chronic form of anger, leading to revenge: the antithesis of love."

Tuke mentions among the physical manifestations of the emotions, such symptoms as: "In the early stage of grief, acute pain induces wringing of the hands, grinding of the teeth, tearing of the hair, sobbing and groaning. . . . In a later stage, grief induces feeble respiratory movements and sighing, and produces on all the muscles very different effects from joy. They are, in fact, the natural result of pain which has been felt to such a degree as to exhaust the system: the flaccid muscles now droop under their own weight, those of the cheek especially tending to produce by their own action on the eyelids the familiar expression of sadness. . . Fear amounting to terror, by causing spasmodic respiration, may, as in grief, choke the utterance, or the voice is husky. The facial expression is that of dyspnea. . . . Fear, if it does not proceed so far in the direction of terror as to paralyze the muscles, induces rapid muscular action in the form of flight, while it fixes and contracts other parts of the body in the instinctive attempt to conceal and, as if it were, diminish their size. . . . The muscular states alike of contraction (or tension) and relaxation find illustration in the motion of terror, for with the signs of the former already mentioned, and the stare of the eye, are combined the relaxation of the masseters, the sphincters and the processes of organic life with which we are not now concerned." . . .

"Rage and anger contract the masseters, inflate the nostrils, expand the chest, furrow the forehead, and expose and roll the eyeballs, clinch the fists, and induce a violent action and more or less rigidity of the muscles generally. . . .

"Contraction, it has been said, is the natural language of the painful emotions; relaxation, of the pleasurable ones, and it is true that in the early stage of grief, we witness violent contractions of some of the muscles. In anger, again the muscles are vigorously contracted; but there are many exceptions to this rule as laid down. . . . It would be more correct to say that the pleasurable or joyous emotions impart expansion to the expression; the painful or sorrowful ones, contraction." . . .

"Relaxation, again, we have seen exemplified in the later stages of grief, in which it results from the exhaustion of pain and despair. In weeping, in which there appears to be relaxation of the muscular fibers surrounding and controlling the mouth, the effort is really due to the powerful contraction of the muscles of the cheek, and especially the *triangularis oris*." The unusual and undue prolongation of the *tetany of grief*, instead of the *relaxation of weeping*, is generally conceded to be of far greater import and seriousness.

Sir Charles Bell expresses the manifestations of terror as follows: "There is spasm on his breast—he cannot breathe freely; the chest is elevated; the muscles of his neck and shoulders are in action; his breathing is short and rapid; there is gasping and a convulsive motion of his lips; a tremor on his hollow cheek, a gulping and catching of his throat; and why

does his heart knock at his ribs, while there is no force of circulation? for his lips and his cheeks are ashy pale." He then continues on grief: "Why comes at intervals the long drawn sigh? Why are the neck and throat convulsed? What causes the swelling and quivering of the lips, and the deadly paleness of the face? Or, why is the hand so pale and ghastly cold? And why, at intervals, as the agony returns, does the convulsion spread over the frame like a paroxysm of suffocation?" His answer is found in that the outward signs of expression of passion in the face and elsewhere cannot proceed from the direct action of the mind. He proceeds: "However strange it may seem to unaccustomed man, it is to the heart and lungs, and all the extended instruments of breathing that we are to trace these effects."

Upon the above quotations Hake Tuke comments: "It is impossible not to see in the oppression of the breathing, and in the expression of the muscles of the face most concerned in respiration, the same effects produced by certain violent mental emotions, which are the result of morbid condition of the heart and lungs, without these mental changes." Tuke continues: "Thus the mind acts figuratively through all the muscles of the body, the limbs, the trunk, and the face; but it so happens that the great group of movements classed under the head of 'expression' are mainly those of respiration, and hence the muscles of respiration may be regarded from Sir Charles Bell's point of view as emphatically, though by no means exclusively those of expression also. . . .

"Joy accelerates the action of the heart and the circulation; the respiration is quickened, and the muscles of the mouth tell the tale, while laughter is effected by a convulsive form of respiration. On the other hand, fear takes away the breath, and produces on the facial muscles the character impressed by dyspnea from pulmonary obstruction. . . .

"By way of summary, it may be said: we suffer pain of two kinds—bodily, as toothache; mental, as grief or anxiety; and when the latter occurs, the outward signs, allowing for differences, are the same as those which are exhibited in the former."

. . .

"Terror, which often causes excessive or spasmodic contractions, sometimes amounting to tetanic rigidity; the sobbing of grief, the laughter of joy, afford daily examples of spasmodic muscular contraction from emotional stimulus. The spasm which chokes the voice and converts the fibres of the *platysma myoides* into rigid cords in terror, the convulsion and tremors of the facial muscles in despair, the clinched hands, the convulsive opening of the mouth and spasm of the diaphragm and muscles of the chest in fear, the spasm of the jaws in rage, the spasmodic rigidity of the muscles in a maniacal paroxysm—are they not written in the graphic pages of Bell?"

Charles Darwin, in his classic work on "Expression of the Emotions in Man and Animals" says of the manifestations of anxiety, grief, dejection, and despair: "The circulation becomes languid; the face pale; the muscles flaccid; the eyelids droop; the head hangs on the contracted chest; the lips, cheeks, and lower jaw all sink downwards from their own weight. Hence all features are lengthened; and the face of a person who hears bad news is said to fall."

. . .

"The breathing becomes slow and feeble, and is often interrupted by deep sighs. As Geratiolot remarks, 'Whenever our attention is long concentrated on any subject, we forget to breathe, and then relieve ourselves by a deep inspiration; but the sighs of a sorrowful person, owing to his slow respiration and languid circulation, are eminently characteristic.' (*De la Physionomie,* pp. 53-367. On sighing, p. 232.) As the grief of a person in this state occasionally recurs and increases into a paroxysm, spasms affect the respiratory muscles and he feels as if something, the so-called *globus hystericus,* was rising in his throat. These spasmodic movements are clearly allied to the sobbing of children and are remnants of those severer spasms which occur when a person is said to choke from excessive grief." (Sir C. Bell, Anatomy of Expression, 3rd Ed., 1844. p. 151) p. 1791.

Bain, in his well known work on the "Emotions and the Will" has aptly defined anxiety, suspicion, etc. "The term anxiety represents the condition of fear with reference to our various interests that are apt to be more or less imperilled. The rational and measured exertions to meet our known emergencies may be said to indicate anxiety of the mind. Yet the phrase is not properly applicable unless there be present something of the perturbation of fear. The anxious condition of mind is a readiness to take fright in connection with our most vulnerable points on all occasions of apprehension or uncertainty. As no one's future can be clear throughout, there is never wanting the matter of anxiety to a mind susceptible of the state. The lives of some are spent in a constant flutter of agitation, varied by moments of inexpressible relief."

"The term Suspicion expresses the operation of our fears upon belief. The state of alarm being by its very nature the breaking up of our confidence, things in general become the objects of distrust."*

In cases of so-called reflex irritations, the climax of manifestation is attained only after time flaccidity and hyperesthesia are produced at the distal point of irritation. Eye strain is now quite generally recognized as such a factor. Congenital phimosis and adherent prepuce and clitoritis are not infrequent causes of acquired deformities in children, especially those of reflex muscular contractions. The cicatrices of lacerated cervixes, of burns, etc.; reflex disturbances from flat foot strain; and the more severe reflex manifestations from certain diseases of articulations are all significant examples of transmission to a distant area of initial tissue irritations. As is well known, so-called nervous exhaustion, spasms, convulsions, tetanic contractions, and a whole list of sequences, result from such transmissions of the initial reaction manifestation to some distant part.

In many of these instances, the tissue of original causation is kept in a state of continual flaccidity and hyperesthesia, and this biologic phase is thus the real cause for the exaggerated reflex transmissions which are so typical, and not an exaggeration of the nervous function as so commonly conceived by superficial observers.

Whatever be one's theory of the mechanism of the transmission of exciting causes of emotional manifestations, one fact rises in importance above all others, and that is that the real index of the vital reaction of the muscular system is the phase of the

*The same ambiguity is seen in Dr. Thomas Brown's exposition of what he calls the prospective emotions. "With him fear is simply the contrary of desire. These are some of his expressions: 'Our fears, which arise equally from the prospect of what is disagreeable in itself, and from the prospect of the loss of what is in itself agreeable.' 'We fear to lose any source of pleasure possessed by us, which has long been an object of our hope.' The want of a good term for the opposite of desire is probably the reason of this abused application of 'fear' to denote simply what stimulates efforts of avoidance. The true antithesis lies between fear and coolness, composure, or measured expenditure." (p. 163.)

biologic series in which said muscles preexist up to the time that their reactions are induced. In other words, the morphological index, the tissue density which varies parallel with the acuteness of the response phenomena of the muscles, is a criterion of the reaction producible by unit factors of stimulation, or perturbation.

In fact, in the higher animal organisms, including mankind, the tissue density governs the degrees of acuteness of excitability ranging all the way from hyperesthesia to anesthesia, together with its corresponding elicitation of response, similar to the most rudimentary forms of life.

The excitability and corresponding reaction of the tissues follow their state of density and biologic series phase so closely that little room is left for the alleged modifications of purely nervous origin.

The hyperesthetic stage of protoplasm reaction characterizes the so-called emotional temperament, the "nervously predisposed," etc. Those prone to hysterical attacks on slight provocation come in the same class. Children on the verge of chorea from fright or other causes, are also in a continual stage of hyperesthesia. Involuntary movements among children and also some adults are due to the same phase of tissue reaction. Emotions are reactional states and they occur either from tissue hyperesthesia or a correspondingly more forceful causative factor.

Undue activity is not due to or associated with great strength. Exuberance in children is not an indication of endurance or strength. Powerful individuals are slow movers, weak ones are generally active, often swift, even if jerky, as characterizes cardiac and other cases of short limitations.

Infants and children, with their immature tissue cells and succulent muscles, are as correspondingly exuberant as the adult in the prime of life is slow moving in the full strength of his adult and dense tissues. All through the biologic series, the phase is characterized by both density and function.

The significance of marked respiratory disturbances, with their resulting suboxygenation of the blood and ultimately the tissues, should be apparent to any medical man. When an equal suboxidation is due to cardiac incompetency or anemia, it is recognized quickly enough, and it receives proper recognition and attention, yet it is no more serious than the same when produced through the senses and the intellect. Not only are serious and deadly diseases caused by prolonged bearings of mental and emotional factors, but sudden death is not an unfrequent sequence when a weak heart or other contributing factors of importance coexist.

The physical status of the depressing emotions corresponding to their degrees of suddenness or abruptness and force, is a contractile manifestation of the peripheral or superficial tissues, exhibiting the faculty of expressing the blood from the principal seats of oxidation in the muscles and skin, into the great visceral reservoirs, largely the great splanchnic veins, thus attaining in some degree to the venous stasis of the moribund condition, and to one involving such obstruction to the blood circuit as to exceed the projecting capacity of a weak heart.

We observe in the so-called mental states, conditions ranging from a prolonged tetany of the superficial tissues to the state of shock or syncope in which the most pronounced effects are present and the blood is most deflected from the seats of oxidation compatible with life.

It is the vital reaction of the tissues to suboxygenation that involves the manifestations of dyspnea and other forms of expression of suffocation or asphyxiation, and these response phenomena are expressed in relation to the reaction vitality of the tissue or animal body. It is evident that the exclusion of the blood from the capillary circulation of a large percentage of the body, excites the same difficulties of oxygenation and elimination of carbonic dioxide as when the same ultimate effect is produced by other factors accomplishing the same result. It is not clear how such causes act through the so-called respiratory center in the medulla, but conversely it would seem to offer good evidence that the respiratory center of the medulla is not an exclusive center or presiding organ, but rather an area, the asphyxiation of which, like perhaps many others, excites efforts at compensation.

The fact that Mind is the functional product of the brain and is dependent like the balance of the body upon the blood supply and the processes of oxidation and nutrition, is attested by the observation that when the blood is deflected to the venous trunks as exhibited in pronounced terror, for example, the intellect and the will are no longer at the command of the victim, for the brain, as well as the muscles, is paralyzed, so to speak, by the asphyxia of exsanguination.

But one logical conclusion is permissible, and that is, that through the medium of the senses and the intellect, or more physically through the organs of sense, extrinsic impulses, of a nature incompatible with the normal equilibrium of the recipient, are transmitted through the nerves and brain, unbalancing principally the circulation and distribution of the blood, and thus finally the oxidation processes of the body, by virtue of which the whole body, not excepting the brain and its functional product, the mind or intellect, suffers dire consequences in accordance with the nature and force of the external impressions, be it an abrupt action resulting in a blood clot apoplexy, in epilepsy, chorea, or mania, or a long continued peripheral tetany, venous stasis, and anemia leading to cachexia and perhaps melancholia, chronic nephritis, diabetes, cancer, or to an earlier death by an intercurrent infection, to which the antecedent condition has predisposed the subject.

Whenever the student of etiology thoroughly grasps the true significance and importance, nay, *necessity*, of oxidation in the life processes, he will appreciate the true rôle of the so-called mental factors of etiology, and he will not be obliged to become a faith healer or a "Christian Scientist" to fathom their mysteries or to treat them as physical rather than mental ailments.

The treatment of peripheral exsanguination and splanchnic venous stasis, however produced, by mental or physical traumatism, is the same; namely, that of the physical treatment and management of shock, that of rehabilitating the peripheral circulation by surface heat, stimulation, and massage, and hypodermatic injection of ergot by Livingston's method.

It is a reproach to our profession that we have not long ago taught students of medicine and educated the laity on these fundamental problems. We have permitted ourselves to conform to theological dogma so long that it is now a problem how best to throw off this yoke of oppression. Mental healing, securely based upon doctrines manifestly untrue, has thrived while the profession of scientific medicine has suffered in silence, and for no other tangible reason except that no one has the temerity to speak out the truth for fear of offending the theologian.

I cannot close this paper without quoting from Lagrange's splendid work on the "Physiology of Bodily Exercise", which so aptly elucidates the physical basis of emotional factors, and well illus-

trates their contributory cooperation with other physical factors.

"Every violent physical sensation, wherever situated, will react upon the lung; every powerful moral emotion, whatever its cause, will also make its influence felt on the respiratory function. Joy, sorrow, fear, can produce reflex effects on the respiratory movements which we call a laugh, a sob, a sigh, a cry. Every time that the rhythm of respiration is disturbed, breathlessness is produced, even in the condition of muscular repose. . . .

"An exercise which is performed with tranquil breathing if the mind is free from care, promptly produces respiratory disturbances if the mind is brooding and preoccupied. Those who have acted as seconds in a duel to men accustomed to the use of the sword, know that they become breathless in the duel much more quickly than they do in a fencing school. . . .

"Depressing emotions make their effects felt on the respiration of animals as well as of man. A sensitive horse which is badly used when at work, or even roughly spoken to, quickly becomes breathless. . . .

"The dog is incomparably less swift than the hare, but is able to catch it; the fright of the hunted animal disturbs its breathing and robs it of much strength. . . .

"The defect of coordination, the disorder of the respiratory movements which we observe under the influence of fright, much resembles the incoherence in the movements of the lips which prevents a man, deeply moved, from clearly articulating his words. It is thus that depressing emotions can bring on a kind of *stammering* respiration. The disorder of the respiratory movements destroys the regularity of the gas interchange which takes place in the lungs between the venous blood and the atmospheric air, and thus profoundly hinders the function of aeration of the blood. . . .

"The more impressionable the subject, the more easily do emotions influence his respiratory actions. Hence the superiority in certain bodily exercises of men who are calm and masters of themselves.

"If we find ourselves before a man panting from terror, we might fancy he was out of breath from fast running. In both cases there is the same picture: breathing irregular, speech interrupted, complexion livid." (p. 88-89-90.)

The undue softening and coalescence of disorganized tissues, from emotional as well as the more tangible physical causative factors, and the final desiccation of such tissues, accounts for the arteriocapillary fibrosis and premature senility so commonly attributed to emotional factors of etiology, especially worry, anxiety, and grief.

MARRIAGE FROM A MEDICAL VIEWPOINT.

By CHARLES GREENE CUMSTON, M.D.,

BOSTON, MASS.

The study of marriage from a medical standpoint should logically be divided into two distinct questions, namely, health in the immediate physical or normal marital relationship, and, secondly, the health of the husband and wife from a purely hereditary viewpoint. In point of fact, we cannot limit ourselves to the simple consideration of heredity, because, before the birth of a son, the progenitors have lived a common life for a variable length of time, and to be rational, we owe a large portion of our considerations to the influence of health over the first months of matrimonial life. It has been said, from the moral standpoint, that marriage is a vast lottery, but this saying perhaps better belongs to the social status of modern unions. Defects of a personal nature have been so common in our present society that we rarely meet with those whose atavism is virgin to all imperfections or to pathological stigmata. As we look about us we unfortunately see only too commonly young married couples who have been devastated by that fatal disease, insidious and foudroyant phthisis, or some mocking neurosis. The number of young people who, instead of the hoped-for happiness, only find decay and death at the conjugal hearthstone are legion, and many neurologists are of the opinion that unfortunate marriages furnish an enormous contingent of neurasthenics. Perhaps this remark may be commonplace to-day when divorce is so much in vogue, but it nevertheless is instructive for those who look for peace and happiness in marriage.

Tuberculosis, neuroses, gonococcic infection, chlorosis, dyspepsia, and sexual perversion are diseases in which improvement or aggravation may result from married life—a fact important to mention.

Before, however, taking the above-mentioned conditions into consideration, I would like to refer to one cause of danger, which, perhaps belonging more to the domain of morals than physiology, certainly exercises a marked influence upon matrimonial biology; I refer to precocious marriage. To-day, when the struggle for life has become more ardent and difficult, and marriage is too frequently looked upon as a source of pecuniary benefit, precocious marriages are on the increase. I am perfectly willing to admit that in normal subjects genital life becomes rapidly sufficient for fulfilling the exigencies of married life. At the age of eighteen the majority of young men are quite capable of fulfilling the functions of progenitor and of procreating, physiologically at least, a healthy family. But excess in coitus fatally produces serious nervous depression and predisposes to medullary diseases. A husband too young, having constantly within his reach the causes of intense sexual excitement, being able to satisfy them easily, is apt to make an abuse of sexual intercourse and enters life in a dangerous condition. For this reason it is not infrequent to see young people who have married young become neurasthenics, especially if an arthritic or nervous heredity predisposes them to neuropathy.

It is not to be supposed for a minute that excessive venery is the only thing which is unfortunate in precocious marriages. A young man, thoroughly understanding his duties as a husband and worried by the serious charge that he has assumed, the moral preoccupation, the present greater difficulty for making a living for two, and the continual thought for the happiness of the wife bring about more quickly than excessive coitus a morbid hypotension of the nervous influx. Every form of worry is a cause for the development of neuroses, psychasthenia, or the various phobias. The worry resulting from marriage in a man who has entered into it precociously and who is thoroughly penetrated by his conjugal duties, may result in serious changes in his general condition of health as well as his mental faculties.

By precocious marriage, I mean those which are contracted by the male from 18 to 20 years of age. At this time of life, man is developed neither for the daily struggle for his bread, nor for genesic excess to which his youth and his active tempera-

ment and lack of will control over himself expose him. This fact has been acquired from general experience, namely that precocious marriage is bad, especially in the case of individuals whose nervous or uricemic heredity predisposes to neurasthenia, and the same may be said of those who are in a debilitated condition from an impoverishment of the blood. Excessive youth or old age of husband and wife, or of either one of them, is certainly without a doubt a cause of debility in their offspring and the oriental custom, authorized by law, of marrying very young can itself explain the decadence and infantilism of certain races.

To sum up, marriage should never be advised to youths under the age of 20 at least, and it is incumbent upon the physician to show them the many physiological and moral inconveniences resulting therefrom.

A question which unfortunately is of the highest interest at the present time is that of the marriage of tuberculous subjects. Much has been written on this question, but from the start it may be said that there is tuberculosis and tuberculosis, there is not a single tuberculosis, but tuberculoses. This common affection is not met with as a morbid entity with an identical symptomatology, and, in my opinion, pathology has been too greatly systematized, and authorities have endeavored to classify, to concentrate pathological manifestations under a single head, when in reality they offer a great disparity. In order to facilitate the study of pathology, there has been too much cataloguing and labeling; it is the day of divisions and subdivisions, so that the textbooks on pathology will soon take the place of clinics and make the study of medicine in the library an easy matter.

In most instances practical experience denounces theory. Medicine cannot be learned by books alone, and its knowledge must be largely accumulated by direct observation. At the present time our students are far too savant, and, so to speak, not artists enough. This paradox is justified in the subject which we are treating, and it is to be noted that the large majority of authorities discourage marriage to tuberculous subjects as much for them as for those with whom they are in daily contact and their future offspring. Many practitioners, relying upon their books, settle this delicate question ex cathedra, while others, who are more easily touched by pity, hesitate to emit any opinion, being divided between the fear of making a mistake and the very scrupulous fear of rendering a man unhappy forever, perhaps wrongly. As I have pointed out, every excess is a mistake, and to prevent marriage in every case of tuberculosis is, I believe, a useless cruelty, while to tolerate marriage in all cases of tuberculosis is a most dangerous imprudence, and there are two sides to all these cases. According to the nature, symptoms, and degree of the tuberculous infection, the physician should, and must, reason. In those cases in which the development of the disease is rapid, at the same time presenting a particular nervous erethism, making itself evident by early loss of flesh, severe hemoptysis, fever, and dyspnea, marriage would naturally result only in a fatal outcome, and coitus alone might bring about a fatal pulmonary hemorrhage. In these instances ordinary common sense indicates the advice to be given, but, on the other hand, it is a much more delicate affair to advise for or against marriage when one is dealing with cases of torpid tuberculosis, where the progress of the affection is slow and cure appears to be obtained easily. Certain eminent authorities advise against marriage, but there is a fact which seems to have been proven by daily observation, namely, that marriage has generally a favorable influence over tuberculosis with a slow progress, more particularly when matrimony coincides with the first stage of the disease.

Since I make this assertion, it is necessary to give my reasons, and they are these: Marriage regulates life and renders it more stable. A man who weds a woman who is dear to him, and who returns his love, will be greatly improved from the mere joy of living in the midst of affection and devoted care, and from this fact it is not at all astonishing that in instances of slightly advanced tuberculosis, the patients eating at regular hours, leading a calm and regular life, enjoying the well-being that an agreeable, conjugal life can alone give, are rapidly placed in biological conditions excellent for the production of a cure. The powerful influence possessed by the moral over the physical side of man is well known, and it is not at all surprising that in a happy frame of mind these patients note the return of their strength and a return to health. For all these reasons, it would seem most irrational to prevent a patient from marrying simply on the ground of medical tradition.

Relative to tuberculous heredity I will speak later, and for the present I wish to consider the relationship between health and marriage simply from the point of view of the husband and wife. From this viewpoint tuberculosis is far from always being a contraindication to matrimony, but, quite on the contrary, the disease may be ameliorated by marital life. There are, however, certain rules which should be followed; clinical observation has shown the tendency of tuberculous subjects to abuse the act of coitus. What I have already remarked when speaking of early marriages also finds its place here. The ease of satisfying the genital instinct will surely bring tuberculous subjects, especially those who are at their first period, to a state of biological inferiority, fatal to those who are in a somewhat weakened condition. Therefore, for this reason, it is incumbent upon the physician to warn these subjects in this respect in order to avoid disaster.

Another question of great interest is that of the dangers of pregnancy complicated with tuberculosis. Independently of the hereditary taint, gestation is a serious danger for the tuberculous. Parturition requires a consummation of strength and nutritive materials that these subjects can furnish only with detriment to their future health, and for this reason pregnancy should be advised against.

To sum up, it may be said that the marriage of tuberculous subjects should be prohibited only when formal indications exist; it should be tolerated on the condition that they are given a full understanding of the necessary hygiene to follow, but this only in cases which are in the early stages and capable of cure.

Much can be said in regard to the marriage of neurotics, because the various neuroses are at the present time extensively developed; the accumulated hereditary defects, the intense life now led, the abuse of alcohol and tobacco are all causes which contribute to the development of neuroses, neurasthenia and hysteria, and simply hasten the development of medullary diseases.

I am led to believe that marriage in neurotics has perhaps more influence than in any other type of affection. When one considers how important love is in nervous pathogenesis and the depression following in these subjects when they are opposed in

this respect, the loss of a wife or the separation of lovers, refusal of marriage, all of these conditions develop nervous and mental troubles in those who are predisposed, and frequently the ultimate outcome is suicide. Neurotics, more than other people, experience a special intensity, the joy and pain of love, and a tender affection fills them with a healthy force, while a deception or an infidelity may result in their ruin.

An improvement after marriage has been not infrequently noted in the case of melancholia, and the fulfillment of the conjugal act has a powerful, sedative effect in certain cases of hysteria, while it is well known how a calm and regular life with the tranquil atmosphere of the household is favorable for the cure of neurasthenia. All this can readily be understood on account of the influence of joy and happiness upon the nervous system; the nutritive changes are increased, the appetite likewise, the hepatic functions become regular, sleep repairs, and strength becomes more marked. Psychotherapy is a very powerful arm against many neuroses, and there is no suggestion or moral action more efficacious than that which imperiously rises in a human soul from the natural concourse of circumstances. Happiness is without doubt the best form of rational psychotherapy, and may be considered as the ideal tonic of the neurologist, and from all this it follows that a marriage, when desired by a nervous patient, is, in many instances, a therapeutic measure of considerable importance in the cure of the neurosis.

Another cause enters in the explanation of the happy influence of marriage on certain neuroses, namely, the regularity of life in eating and sleeping. A large majority of authorities incriminate as a cause of neurasthenia and certain mental affections, the intoxication produced by irregular meals, an excess in the meat diet, the rapidity of mastication, the use of alcohol in various forms, overindulgence in tobacco, irregularity in the hour for retiring and rising, all of which are done away with when married life is entered into, because habits become regularized and disciplined. I am far from believing, however, that such a fortunate outcome can be always realized, and there are psychopaths for whom married life is a perfect hell. Certain forms of hysteria develop from the fact of being married and renders the life of the healthy conjoint very unhappy. We all have encountered hysterical women who are excellent wives and good mothers, but when consulted relative to the question of marriage, it is always well to advise circumspection to a young person when the future partner appears to be too romantic in ideas, or when they are markedly original in character. Under these circumstances, the advice of a physician should be brought to bear and the antecedents, both personal and hereditary, should be carefully gone into in all instances of young people having a peculiar character. It is very important because upon the result rests future happiness or misery.

Insanity and epilepsy naturally are conditions absolutely prohibiting matrimony.

To sum up, it may be said that matrimonial life in the case of neurotics is a very frequent cause of an improvement in neurasthenia, the result of overwork, of poor hygiene, melancholia, and certain trifling mental disturbances produced by over-fatigue, on account of the regularity that it brings to all the acts of life. Latent hysteria should not be considered as a serious hindrance to marriage, but it, nevertheless, is well to ascertain all points relating to the pathological antecedents of the future wife.

Recent statistics show that the number of gynecological operations necessitated by gonococcic lesions increases every year. The story is always the same. A woman, either after labor or without any apparent reason, complains of severe pain in the lower abdomen. She becomes anemic, complains of lassitude, and passes all her days on a lounge; menstruation becomes painful and irregular, and when the physician is consulted he finds a metritis, salpingitis, or ovaritis, and concludes that a surgical operation is necessary. Happy is the woman who does not develop a rapidly forming pelvic abscess, or a serious peritonitis. The husband, either criminally or unconsciously, transmits the gonococcus to his wife, usually in the following manner: In his bachelor days he contracted a gonorrhea, which was treated according to the usual methods—that is to say, with contempt—the gonorrhea disappears, but leaves in its place an insignificant gleet, a chronic discharge of such apparently little importance that the patient neglects to have it treated, supposing that it will cure itself. Upon this he gets married, usually without any thought of the past and without consulting a physician as to the seriousness of his little morning drop. After a variable length of time, and as soon as a congestion of the uterus predisposes the organ to microbic receptivity, the young wife presents all the well-known symptoms of a gonorrheal infection.

To a certain extent the public has surmised the dangers accruing from this disease, but not to the extent that it should. In face of the terrible consequences to which gonorrhea may give rise, the mortal dangers to which the spouse is exposed, sterility following gonococcic complications, certain members of the profession have declared open war against gonorrheal subjects guilty of contamination. In Germany especially a law is under consideration which tends to protect women against venereal contagion from the husband, or even the lover. Professor Hegar, in Germany, and Jullien, Cazalis, and several other physicians in France, have proposed an obligatory verification as to the genital innocuity of the future husband. As a conclusion to this, I would advise that young men be told that, if they are unfortunate enough to contract gonorrhea or syphilis, they should loyally consult a reputable physician before their marriage to ascertain whether or not they are fit subjects for matrimony. It is high time that the profession put an end to public ignorance in these matters, and thus to a great extent avoid many catastrophes and moral pain.

871 Beacon Street.

NOTES ON STERILITY IN WOMEN.

By B. S. TALMEY, M.D.

NEW YORK.

GYNECOLOGIST TO THE YORKVILLE HOSPITAL; FORMERLY PATHOLOGIST TO THE MOTHERIS AND BABIES' HOSPITAL.

Two desires control and govern mankind, one, the desire for nourishment, is founded upon the instinct of the preservation of the individual, the other, the desire for offspring, upon the instinct of the propagation of the kind. The former concerns only the individual, the latter is of a far more reaching importance, from a social as well as an economic point of view. Progeny is of an incalculable economic value to the body politic. Although the age of forty is not just the point in a person's life to be chloroformed out of existence,

yet there does arrive a time in the life of the individual when its usefulness to the community is nil. The individual does not any longer produce new wealth, and what it consumes, even of its own savings, is a direct loss to the sum total of the nation's wealth, except the individual has created new producers in its children who continue in the work of their parents. Sterile marriages are, therefore, a failure even in modern times and even from the materialistic point of view.

No wonder, therefore, that the problem of sterility has occupied the great minds of all times. Among the ancients barrenness was punished by the dismissal of the wife. The Roman law allowed the putting away of the wife for infecundity. The Jewish law allows a divorce after ten years of childless wedlock. Hence married women were since time immemorial in search of fertility and sterility has engaged the attention of the medical profession from the earliest periods.

Before entering upon the discussion of the causes of sterility, let us pass for a moment in review the mechanism of impregnation. When the sperm has been deposited in the vagina, or rather, has been aspired by suction during the organism within the cervical canal, the spermatozoa begin to move towards the interior. The celerity of their motion is, according to Henle, Kramer, Hensen, and Lott, from 1.2 to 3.6 millimeters a minute. They will, therefore, finish their way from the vagina through the uterus and tubes within one or two hours.

According to Bischoff and His, the impregnation takes place in the distal end of the tube. After impregnation the ovum continues its wandering by the current of the ciliated epithelium of the tube towards the uterus. The ovum needs according to Hensen from three to five days, according to Bischoff eight days, to traverse this way. It could not last longer, says Winckel, because the uterine end of the tube has a diameter of only 2 to 3 mm. while the diameter of the ovum in the second week is 3 to 6 mm. When the impregnated ovum has reached the cavity of the uterus, it penetrates through the epithelium into the submucous fibrous tissue of the uterus where it completes its development.

The complexity of the mechanism explains the importance of the presence of perfect organs to facilitate the accomplishment of this great task of nature. Any deviation from the normal condition at any point of the genital canal may cause prevention of impregnation or destruction of the impregnated ovum and thus cause sterility.

The time that has to pass before a childless wedlock is to be considered sterile is not the same with different authors. Chrobak, Rosthorn, and Hofmeier consider a marriage sterile when two years of childless married life have passed, while according to Jaquet two and a half years, and according to Kisch three years have to pass before they call such a marriage sterile.

At the outset two groups of sterility may be distinguished, the sterility caused by the man and that caused by the woman. In regard to the former we could say that not only impotency and aspermia will cause sterility but a certain changed quality of the spermatozoa will render the marriage sterile. According to Boweri the ovum has all the organs and qualities necessary for the development of the fetus except that its centrosoma, which starts segmentation, is in a state of inactivity while the spermatozoon possesses the active centrosoma but lacks the protoplasma, the material, by means of which this organ could begin its activity. Hence when through some cause or other the spermatozoon has lost its active centrosoma the result will be sterility.

But male sterility will be eliminated in this paper and we will consider only female sterility. Here we must again distinguish two kinds of sterility, the primary where no conception has ever taken place, and the secondary where there was fecundation but an abortion has taken place or the child died and after the first conception the woman ceased to propagate.

In considering primary sterility we have again to make a distinction between idiopathic and relative sterility. Idiopathic sterility is absolute and irremediable; treatment is useless. Relative sterility is an anomaly that yields in the majority of cases to appropriate treatment. Under the heading of idiopathic sterility we may name: (1) Absence of vagina; (2) fetal or rudimentary uterus; (3) absence or imperviousness of the tubes; (4) absence or fibrous degeneration of the ovaries.

Relative sterility which is eminently curable has the following causes: (1) Atresia vulvæ; (2) vaginism with the painful tetanic contraction of the sphincter cunni; (3) rigidity of the hymen; (4) carunculæ of the urethra; (5) ulcerations of the introitus vagina; (6) inflammation of the carunculæ myrtiformes or of the Bartholinean glands; (7) hypertrophy of the rugæ; (8) excessive acid reaction of the vaginal contents; (9) one lip of the cervix is considerably elongated, covering apronlike the external os; (10) obliteration of the cervix caused by caustics or scars after tears during confinements; (11) ectropion; (12) stenosis of the external or internal os or of the cervical canal; (13) endocervicitis causing an increased secretion; (14) swelling of the plicæ palmatæ; (15) polypi of the uterus; (16) hypertrophic chronic metritis; (17) endometritis chronica hyperplastica; (18) uterus infantilis or hypoplasia of the uterus; (19) uterine deviations; (20) bilateral salpingitis with swelling of the cervical folds and vili and often with closure of the ends of the tubes; (21) pelviperitonitis, perimetritis perisalpingitis, perioophoritis; (22) hypoplasia of the parenchymatous tissue of the ovary; (23) neoplasms causing pains during coitus; (24) absence of the aspiratory action of the uterus through its imperfect participation in the sexual orgasm.

In idiopathic sterility where there is lack of development of the genital organs it is useless to treat the patient for sterility. Even if we construct a new vagina to make coition possible, this vagina will never serve as the exit of a child.

In rudimentary uterus or even in uterus fœtalis, characterized by the cervix being twice as long as the corpus and the entire organ being long and thin, the organ is beyond repair.

In fibrous degeneration of the ovaries with a complete absence of ova, as the writer once found in a child one year of age, where the ovary was not longer than a pea and the microscopical examination showed it to consist of fibrous tissue only, treatment of any kind is useless.

Contrary to idiopathic, relative sterility is amenable to treatment and may be cured when the cause is removed. For the purpose of the therapy we may distinguish two classes of cases, those in which the lesions are accessible as at the vulva, vagina and uterus and those where the trouble is located in the tubes, ovaries and para- and peri-metrium.

In atresia vulvæ, vaginism, rigidity of the hymen, carunculæ of the urethra and hypertrophy of the rugæ or atresia of the vagina nothing but a surgical operation is of any value. Ulceration of

the introitus vaginæ, inflammation of the caruncule myrtiformes and of the Bartholinian glands will require local treatment. The excessive acid reaction of the vaginal contents destroying the mobility of the spermatozoa, will require alkaline douches.

The hypertrophy of the apron-like cervical lip as well as obliteration of the cervix, ectropion, and polypi will require surgical interference. Deep lacerations of the cervix may cause abortions and thus indirectly sterility. The latter may be cured by a trachelorrhaphy as in the following case:

Mrs. K., seven years married, has two boys living, the younger four years of age. Since her last confinement she had six miscarriages, as a rule in the third month of pregnancy. At the examination two deep lacerations of the cervix were found. Trachelorrhaphy was performed, and six months later the patient became pregnant and carried her child to term.

Stenosis of the os or of the cervical canal may in extreme cases—the popularity of the stenosis and atresia theory of sterility, says Massey, is due to the operative furor—require surgical treatment. But even in such cases slitting of the cervix is too radical an operation to be generally followed. This mutilation removes the stenosis but the result may be habitual abortion.

When the ends of the tubes are closed, as in hydrosalpinx, surgical treatment may be of some benefit. Also abdominal tumors which cause such pains during coition as to render it impossible and thus indirectly cause sterility will require surgical interference.

In uterine deviations a sharp anteflexion could be first treated by a thorough dilatation of the cervix, slight curettage and introduction of Foerster's pessary for eight to ten days. In extreme cases of retroflexio ventrosuspension by the round ligaments as advocated by the writer is of advantage.

All these accessible lesions may sometimes cause sterility but, in regard to frequency, are of slight significance in comparison with endometritis and pelviperitonitis. These two affections are the causes of sterility par excellence and are just the lesions which are seldom or never amenable to surgical treatment. Here electricity is almost the only remedial measure that promises success.

The physiological effects of the electric current take place by virtue of the vital properties of the body through its action on the nerve supply, influence upon circulation, secretory and excretory processes and the acceleration and absorption of morbid products. Electricity promotes the nerve tone, increases muscular activity and quickens circulation.

When the current passes through living tissues the interpolar action of the positive pole is, by contracting the capillaries, anodyne sedative, anticongestive, denutritive and antihemorrhagic. The interpolar action of the negative pole is, by increasing the blood supply, stimulating, congestive, derivative and alternative, thus favoring absorption. The physiological effects of the farradic current are mainly mechanical, producing a veritable interstitial massage.

These physiological qualities make electricity the best remedial agent in the treatment of endometritis, metritis, salpingitis, ovaritis, and pelviperitonitis. Now endometritis and pelviperitonitis are by far the most frequent causes of sterility. Fraenkel says chronic endometritis is the most frequent cause of sterility. Virchow called the attention of the profession to the perimetric inflammations being often the cause of sterility. Rokitansky teaches that perimetric adhesions as a cause of sterility are equal in importance to impermeability of the tubes. When the tubes are buried in adhesions sterility is inevitable; when the ovaries are covered by thick exudative membranes, ovulation is prevented, and only negative electricity with its quality of favoring absorption could remove these exudates. The absorption power of this current which dissolves even good-sized fibroids will surely remove all inflammations and adhesions, provided there is no pus present. In this event electricity is very dangerous and strictly contraindicated. But when pus can be excluded there is no better remedy for endometritis and pelviperitonitis than the electric current. We need only to see at one sitting the dirty mucus leaving the uterus under the influence of the negative pole and we understand how electricity can cure the worst endometritis.

By increasing the blood supply negative electricity acts also like Bier's hyperemia, upon all internal inflammations, but particularly upon chronic endometritis. The latter is seldom benefited by the routine currettage. It has been repeatedly proven beyond the shadow of a doubt that curettage never removes the entire diseased uterine mucosa, but rather leaves its greater part intact even in the most skilled hands. Hence before resorting to curettage electricity should first be given a fair trial. For the deep inflammations as metritis, salpingitis, oophoritis and pelviperitonitis no surgical operation should ever be tried. Cases of sterility that could be benefited by serious surgical operations are very few indeed.

Uterus infantilis is another anomaly that is greatly benefited by electricity. Some times a previous small operation is necessary. Uterus infantilis in itself, says Beizel, does not prevent conception but the conical elongation of the cervix is often so closed up by the vaginal walls as to leave no room between this point of contact and the external os. In such a case the amputation of the cervix and subsequently the application of the faradic current will be of great service.

When the cause of the sterility is deficient activity of the ovaries any remedial agent promoting the activity of the pelvic circulation, *e. g.* massage, will be of great benefit; but here again the best means to promote this desired activity is the uteroabdominal galvanic application.

Sometimes sterility is caused by orgasmus retardatus. Kisch found among sixty-nine sterile women twenty-six with dispareunia. He is, therefore, of the opinion that the sexual excitement of the woman is not irrelevant to impregnation. Fraenkel found in his one hundred cases of sterility the causes to be: dispareunia and lack of libido four times, pains in coition twelve times, and lack of orgasm five times. This deficient orgasm, as shown by the writer, is mostly caused by early masturbation. It is thus a weakness of the nerves and is greatly benefited by an electric tonic.

Nervous weakness is also not infrequently the cause in relative sterility where one child was born and no more children were desired. In such cases impregnation is prevented and the physiology defeated by coitus interruptus for a certain length of time, which weakens the entire nervous apparatus of the genital sphere. When later on, for some cause or other, the woman yearns for another child and the father is anxious for further progeny, they find that their wedlock has become sterile. In such cases no other treatment except the tonic effect of electricity will be of any benefit.

The last class of cases of sterility are those where the genital organs are apparently normal, but the uterus is not able to furnish the necessary nutritive

elements to the growing ovum. It suffices not, says Gruenwald, that copulation of sperma and ovum had taken place and the pregnancy had set in, but it is necessary that the uterus in its texture and nutrition be of such a quality as to be in a position to fulfill its function of furthering the development of the fertilized ovum and bring it to term, otherwise the patient without being aware of the fact may have an abortion almost every month. In such cases very few remedies except electricity will be of any value. The electric current tends to give to the uterus a certain amount of tonic which it requires to harbor the ovum to the end of its development.

The histories of the following six cases taken from numerous similar cases of the writer's private practice will prove the efficacy of the electric current in the treatment of sterility:

Case I.—Mrs. S., 25 years of age, had always had regular menstruation. She has been married four years and remained childless. For the last two years she has been running from one doctor's office to that of another without success. The obligatory stretching of the womb and the so-called cleaning had been performed on her without having the desired effect. The examination showed a large uterus with a thick hard cervix and an erosion. The adnexa were sensitive but otherwise normal. Electrical treatment was recommended and accepted. The patient received at the first sitting—the negative electrode within the uterus—10 milliampères for five minutes, which was increased at every sitting until twenty-five milliampères were administered for ten minutes. Three months later the patient became pregnant and gave birth to a healthy girl at term.

Case II.—Mrs. St. is four years married and sterile. The examination shows a chronic endometritis and an enlargement of the right adnexa and a considerable uterine discharge. The patient received ten treatments, the first two with the positive pole within the uterus to cause a diminution of the discharge. The other applications were made with the negative pole within the uterus. Four months later the patient became pregnant and gave birth to a healthy boy at term.

Case III.—Mrs. A. was three years married and sterile. The examination showed a stenosis of the external os, a narrow cervical canal and anteflexio. In the beginning only a very thin electrode, with the negative pole within the uterus, could be used until the lumen of the os and the canal was enlarged. Thereupon six treatments with the ordinary electrode were given. Three months later the patient got pregnant and gave birth to a healthy boy at term.

The following three histories are of cases of relative sterility.

Case IV.—Mrs. H., 30 years of age, has been ten years married and has one child nine years of age. A year after her first confinement she became again pregnant but had an abortion and was curetted. To avoid any more pregnancies impregnation was prevented by some means or other for about five years. During this time the patient suffered repeatedly from endometritis. For the last three years the couple have wished another child and coition is normal, still the patient does not conceive. At the examination the uterus was found enlarged with a knotty swelling at the left uterine horn. The left adnexa are enlarged, the tube being of the thickness of a small finger. The patient received eight treatments with the negative electrode intrauterine. The uterus became smaller but the knot in the horn and the swelling of the tube had not entirely disappeared. Six months later the patient became pregnant. In the seventh week of pregnancy the patient suddenly had a fainting spell while leaving the bath tub but soon recovered when brought to bed. The following day after a hearty breakfast she had again a spell, but this time remained in collapse for several hours. The examination showed a considerable meteorism of the abdomen, pulse 112, temperature 102° F. and a soft mass in the cul-de-sac. The rupture of an extrauterine pregnancy was diagnosed and the patient operated upon the same evening. The left tube was found ruptured, the embryo of about six weeks floating in the blood which filled the pelvic cavity. The swelling in the left horn was found to be a small subserous fibroid. The ruptured tube with the left ovary, on account of the precarious condition of the patient, was removed en mass. For the same reason the fibroid was left untouched to avoid the prolongation of the operation on a collapsed patient. The recovery was uneventful.

Case V.—Mrs. L. was confined with her first child eleven months after she was married. The child died when a year old. Since her first confinement three years have passed and the patient is still sterile. The examination showed an endometritis and erosion of the cervix. The patient received six treatments with the intrauterine negative pole. Two months later the patient became pregnant and gave birth to a healthy boy at term.

Case VI.—Mrs. M. was curetted three months after she was married presumably to remove the secundines of an interrupted pregnancy, but no traces of a preceding pregnancy could be discovered. From this time on impregnation was prevented by different means for about two years. When the couple then wished a child they found their wedlock sterile. The examination did not reveal any anomaly whatsoever. It was apparently a weakness of the nerves caused by the continuous prevention of impregnation. The patient received six treatments with the negative pole within the cavity of the uterus. Three months later the patient became pregnant and gave birth to a healthy girl at term.

From these six histories taken from the numerous cases of sterility seen by the writer it is easily seen that in cases of sterility caused by a diseased condition of the internal genital organs electricity is, if not the only remedy, the remedy *par excellence*. It is, therefore, to be marvelled at the extreme tenacity of the majority of surgeons to the efficacy of major surgical operations in such cases of sterility.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, August 22, 1908.

FADS IN CLOTHING.

IN these days faddists of every kind abound. The man or woman with a crank is almost more the rule than the exception. To be very keen on any one subject is generally a good thing, for it is only those nowadays who specialize who ever arrive to eminence; but to be obsessed with a subject, or to carry a fad to excess does not certainly lead to eminence, and one who is bitten with the microbe of faddism is generally regarded as a bore. So far as fads in regard to health are concerned, with the possible exception of Christian Science, more noise is made in the world by the individuals who pin their faith to a particular diet or to an especial form of dress. The believer in nuts or in raw foods of one kind or another, or the advocate of extreme abstinence or of unceasing mastication, must declaim from the housetops that the thing which has happened to hit his fancy is the sole condition of health. True it is that, in a month or two, the same man will probably be praising a different diet altogether, but it matters little what the kind may be, the only thing certain is that he will do his best to let all the world hear of it. Regulating one's diet and adapting it to suit one's constitution are excellent procedures, and go far oftentimes to ensure good health, but there is a limit.

The bad effects of a "health" diet are generally obvious, but the harm done by hygienic clothing is not so readily visible. It has been for long a matter of settled opinion that corsets, at least these garments when worn tight, are a fruitful cause of illness among women, and many authorities in matters hygienic have, from time to time, advised women to give up the wearing of this popular form of attire. Dr. Bulstrode, an English expert on all pertaining to consumption, says the chief cause why pulmonary tuberculosis has decreased among English women is that corsets are worn more loosely than was formerly the case. Dr. Lillian M. Chesney, however, in a vigorous and entertaining article, which appeared in the July number of the *Journal of the Royal Institute of Public Health*, attacks the theory of Dr. Bulstrode and many other theories regarding women's clothing, which have come to be regarded as articles of faith. This lady denies that women have given up stays, and says that they are worn quite as much as ever, and further declares that it is not compression around the waist that is hurtful to health, but that garments hung from the shoulders are the injurious ones. The reason given is that, when garments which hang from the shoulders are worn, the apices of the lungs, being unprotected by any bony structures, are compressed, and in unmuscular subjects the constant weight of clothes hung upon the shoulder causes a tendency to stooping.

Again, as to the custom in civilized countries of women partially disrobing in the evening and wearing low-neck dresses of thin material, and thin shoes and stockings, while in the daytime, when the sun is warm, they will walk about with the bodies fully covered. In theory, of course, it is highly unwise to be in the sun, warmly clad, probably with fur or feathers round the neck, and at night to go out lightly clothed, with bare head, or to dance in a hot ballroom and then sit in a cool balcony, in scanty attire and in the thinnest of shoes and stockings. If all happened that should happen persons who thus offend against the laws of health as laid down by "authorities," should pay a heavy toll of ill health and death. As a matter of fact, Dr. Chesney asserts very few women do catch cold in the evenings. It is not the well-to-do who, as the Irish lady expressed it, "strip for the company," who get colds, pneumonia, phthisis, nearly so much as the poor, whose social customs do not extend to dressing, or undressing, in the evenings. There is far more harm, according to Dr. Chesney, in keeping the chest always covered up with woolen clothing than in covering it for one-third of the day and uncovering it in the evening. The writer also expresses her dislike, from hygienic and cleanly standpoints, of wearing heavy undergarments. She is of the opinion that the night sweats of consumption are largely induced by wearing woolen nightgowns and by the habit among the poor of going to bed in half their day clothes. The argument is extended that if, as most modern authorities say, there is benefit in an abundance of fresh, cool air, no danger in wet feet, no harm in draughts for the consumptive, the healthy cannot suffer from them either.

There is little doubt than many persons, at the present day, coddle themselves too much, and it is more or less certain that very many of the common ailments of children proceed from their being too warmly clad. It probably is true, too, that woolen garments are not nearly so hygienic as they were at one time supposed to be. They become sodden with perspiration, and, being very absorbent, take up all the effete matters given off by the skin. Common sense in clothing is as necessary as the exercise of that quality in any other question bearing on health.

THE ETIOLOGY OF CHRONIC NEPHRITIS.

STATISTICS appear to show that there has been a noteworthy increase in the prevalence of nephritis within recent years, as well as in the mortality from this disease. It is possible that this increase is apparent rather than real in consequence of improved methods of investigation and greater accuracy of observation. At the same time it cannot be denied that present-day modes of living may play some part in this connection. Inflammatory changes in the kidney are found frequently after death when their presence during life was not suspected from either clinical or etiological considerations.

Nephritis has been caused experimentally by

means of various toxic substances, but the resulting lesions are not identical with those so commonly observed in human beings. An almost constant feature of the latter is some grade of circulatory disturbance in the form of venous hyperemia or local anemia, or both together, and it has been thought that this may be the sole etiological factor in some instances. With a view to determining the influence of such circulatory changes on the function and structure of the kidneys Dr. Haven Emerson (*Archives of Internal Medicine*, June, 1908) undertook an experimental inquiry into the effects of repeated inhalation of general vasodilators, of mechanical injury to the kidney, of injection of alcohol, adrenalin, and physiological salt solution into the substance of the kidney, of increased viscosity of the blood from introduction of gelatin into the circulation, and of intravenous injection of adrenalin and lead acetate. As a result of these observations it would appear that interference with the blood-supply of the kidney can be brought about by means of chemical injury to the renal parenchyma, and that the process of repair that ensues may involve such a destruction of secreting tissue as to cause the death of the animal. In consequence of the use of general vasodilators the kidney suffers at least a mild grade of degeneration, which may be due not to the specific renal irritation caused by the drugs employed, but to the defective blood supply resulting from frequently repeated vascular relaxation.

An analysis of the accepted causes of chronic nephritis in man shows that a common factor in many of these is a more or less severe and prolonged stagnation in the renal blood-supply, and although this factor is often associated with the presence of irritants capable of injuring the tissues of the kidney, an insufficient supply of blood alone will cause first an error in the function and later an alteration in the structure of the kidney. Cardiac disease, bacterial toxins, and metabolic waste-products are probably the causes of the errors in circulation that bring about the changes mentioned. Accordingly, the prophylaxis consists in increasing present efforts to check the spread of infectious disease, and the correction of habits of over-stimulation and overwork, so prevalent in large centers of population.

NERVE SUTURING.

Partial or complete division of a nerve, sufficient to impair its function, may be spontaneously recovered from, but such a fortunate occurrence is not to be relied upon. In the *Centralblatt für die Grenzgebiete der Medizin und Chirurgie* (May 7, 22, and June 5) Ernst Oberndörffer reviews the entire literature on the subject. He collected 287 cases and found that in 128 the nerve injury was caused by a cut, in 46 by a stab, in 38 by a fracture, and in 22 by a severe contusion. In judging the results of neurorrhaphy he took into consideration the motility of the muscles alone; 72 per cent. were cured, in 15 per cent. the result was poor, in 13 per cent. doubtful. The result of the operation depended mostly upon the kind and extent of the injury and whether the wound was infected or not. The age of the patient, the distance of the injury from the spinal cord, and the after-treatment had little effect on the final result. The results following secondary suture were as good as those following primary suture, provided the former was performed within six months after the injury. It usually took from two to twelve months after operation before any improvement set in. The nerve injuries caused by a cut or severe contusion were usually sutured primarily, as the accompanying injury to the parts ordinarily required surgical attention. Those due to fractures or bullet wounds were usually sutured secondarily.

From Obern dörffer's statistics we see that two-thirds of the cases of neurorrhaphy were successful. Where there is a large wound the function of the nerve should be tested immediately, and if found impaired the severed nerve should be sutured at once. In fractures the nerve is usually not affected until a callus forms, but even if it is divided at the time of injury neurorrhaphy had best be postponed, as it would hardly seem wise to make a compound fracture out of a simple one. We may say that unless there is a large wound the treatment of nerve division should be expectant provided the nerve suture is performed within six months after the trauma. The operation has certainly been performed frequently enough and with sufficient success to justify repetition.

The Position of the Heart in the Presence of Pericardial Effusion.

Divergent views are held by different observers as to the position of the heart in the presence of an accumulation of fluid in the pericardial sac. By some the heart is said to be displaced downward and backward, others assert that it is pushed upward and forward, and still others that it retains its normal position. In all probability the heart occupies various positions under the conditions named in accordance with the varying physical factors present in individual cases. With the object of determining these factors and their action, Dr. W. J. Calvert (Bulletin of the Johns Hopkins Hospital) made a careful study of sections of the hardened bodies of two individuals with pericardial effusions at the time of death. It was found that the position of the heart in the presence of a pericardial effusion is governed by the size of the heart and that this depends upon the degree of distention of the heart or on the amount of blood contained within it. The latter in turn varies with the stage of compensation. So long as compensation is maintained the heart contains a relatively normal amount of blood and occupies a relatively normal position. When compensation fails the amount of blood delivered to the heart is diminished and the heart becomes smaller and smaller until collapsed. The size of the heart varies inversely as the pericardial pressure. During this change in size the heart successively occupies positions varying from normal to one in which it comes to lie against the posterior wall of the pericardium. The apex is in a normal position or displaced backward and slightly to the right; otherwise it is unchanged. When the pericardial pressure is high or when compensation is failing the signs should be a triangular area of dullness, high pulse-rate, perhaps pulsus paradoxus, low arterial tension, marked systemic venous congestion, and pronounced pulmonary symptoms.

Serum Injections in Hemophilia.

In the greater majority of cases hemophilia is an hereditary constitutional fault, at times, however, it is acquired. The symptoms of both varieties are similar and well known, and in both the coagulation time of the blood is much retarded. In a recent issue of the *Revue pratique d'obstétrique et de pédiatrie,* P. E. Weil differentiates between the accidental, transitory, and the congenital variety; in the former he found the blood to be thin and to flow rapidly through a needle inserted into a vein; the leucocyte count was normal, and the coagulation time was seventy-five minutes, the coagulation being solid and the serum plentiful. In the congenital variety the blood was sticky and flowed slowly, there was an increase in the percentage of uninuclear leucocytes, and the coagulation time was from two to nine hours, the coagulum being soft and the quantity of serum small. Weil found that when three minims of animal serum was added to three cubic centimeters of blood, taken from a patient suffering from either variety of hemophilia, coagulation occurred in five to ten minutes. When he injected ten to twenty c.c., of normal blood intravenously, or twenty to thirty subcutaneously into these patients, he found that the coagulation time was practically normal two days after the injection, and remained so several weeks, this effect being a little less marked in the congenital variety. He also found that normal serum applied locally had a styptic action. Weil therefore advises the injection of normal serum, or, if such cannot be had, diphtheria antitoxin, for the bleeding in hemophiliac patients in whom styptics, compresses, ergot, ice, calcium lactate, gelatin, etc., have been unsuccessful.

Chloroform Anesthesia and Exclusion of Part of the Circulation.

Since interference with respiration and failure of the heart are so liable to occur during the administration of chloroform, any new suggestion which may diminish the frequency of these complications or aid in their treatment is deserving of trial. About a year ago Klapp suggested tying off the extremities temporarily during a chloroform anesthesia, as in this way part of the blood was excluded from the general circulation. Thus less chloroform would be required to obtain the same degree of anesthesia, it being a well-known fact that the smaller the amount of circulating blood the less choloroform will be needed. Recently Ziegner (*Medizinische Klinik,* No. 17, 1908) proved the usefulness of Klapp's suggestion in a series of animal experiments. He actually found that much less chloroform was required to bring about the same degree of anesthesia, when the animal's extremities were tied off than when this was not done. He furthermore found that when animals had their extremities tied those which had the ligatures cut immediately after the anesthetic was stopped, recovered much more quickly than those in which the ligatures were left in place. The less chloroform used the less likely complications are to set in during the course of an anesthesia, and as the severity of the after effects is directly due to the amount of the anesthetic which the organism has to eliminate, it is necessary to limit the quantity given as much as the exigencies of the operation and the patient will permit. In those patients in whom we fear complications or severe after effects Klapp's suggestion would be advantageous in that less chloroform is necessary. Ziegner's experiments also demonstrate that in cutting out a part of the circulation during an anesthesia we have a valuable remedy in combating any interference with respiration and heart failure, for upon removing the ligatures blood not loaded with chloroform immediately reaches the vital centers and acts as a most powerful stimulant.

News of the Week.

Health Conditions in the Canal Zone.—The report from the Department of Sanitation of conditions in the Canal Zone during June, 1908, shows a death rate per 1,000 of employees of 12.35, a reduction of 15.18 as compared with the rate for June, 1907. Among white employees the rate in June, 1907, was 21.05, in June, 1908, 19.84; among colored employees, in June, 1907, 29.96, in June, 1908, 9.46. In the city of Colon the rate decreased 4.53, but in Panama City there was an increase of 8.04. The high rate is said to be due to the prevalence of tuberculosis and digestive diseases of children, and the increase is partly explained by the fact that the rainy season is one month earlier than in 1907, so that comparison of June, 1908, might more fairly be made with July, 1907, in which case there would be a reduction of 6.01. The improvement in the colored death rate is due to the general and progressive sanitary improvement, as well as to improved feeding methods, better bedding and clothing, and gradual adaptation to the new environment. There were five deaths from malaria, two deaths from typhoid fever, and five deaths from pneumonia, all showing a considerable decrease from last year. Of forty-seven deaths among employees, twenty-one were due to accidental violence. Two deaths occurred from rabies, the first instance so far as could be ascertained in which the disease had been reported from Panama. It was thought that a dog in the incubation stage had been imported from the United States.

Tuberculosis in Syria.—Dr. Mary Eddy, an American physician in Beirut, Syria, has established a sanatorium for the treatment of pulmonary tuberculosis on the heights of Mt. Lebanon, Syria. An English trained nurse has been installed as matron, and the consulting physician is Prof. Harris Graham, a Canadian. The dread of tuberculosis is very great in Syria; patients are shunned more than those suffering from leprosy, and in many cases are deprived of proper care. Up to the present there has been no place where they might find shelter and treatment. The new sanatorium has eighteen rooms and a group of tent houses for open-air treatment of men patients. It is situated at an elevation of over 3,000 feet and is surrounded on three sides by pine groves.

Cholera in Russia and the Philippines.—Since the outbreak of cholera in Russia and up to August 13, 225 cases and 150 deaths were registered at Tsaritsyn, where the epidemic has been most severe. The city of St. Petersburg has been officially declared to be threatened with the disease, and bacteriological examinations have revealed the presence of the cholera bacillus in the water of the River Volga. Eleven cases of cholera have been reported in Iloilo, Philippine Islands, and a soldier in camp near Manila has been stricken. Manila has so far been free from the plague.

Rabies Decreasing.—The New York State Department of Agriculture announces that whereas about six weeks ago thirty towns in the State were

under quarantine for rabies, there are now only twenty. The muzzling ordinances are being rigidly enforced.

Street Accidents in New York.—The Public Service Commission requires that the street railway companies notify it of all accidents occurring on their lines, and reports that for the month of July there were 239 serious accidents, 63 less than in June. In these 35 persons were killed and 13 suffered fractured skulls. In all, 3,578 persons were injured.

New York's Death Rate.—For the week ending August 8 the death rate in the entire city was 16.74 per 1,000. Last year for the same week the rate was 22.22. The total number of deaths for the week in 1907 was 1,825; in 1908, 1,419. There were 328 deaths of children under five from diarrheal diseases, as against 486 in 1907.

Charitable Bequests.—The will of the late Mrs. Annie L. Lowry of Philadelphia provides for the distribution among some twenty-one homes, hospitals, and charitable institutions in and about Philadelphia, of over one hundred and sixty thousand dollars. The endowment of several hospital beds is provided for, and in addition the Mission to the Lepers in India receives $3,000. One thousand dollars is left to Finley Hospital of Dubuque, Iowa, by the will of the late Senator Allison. The Deaconess' Training School and Wesley Hospital of Chicago have each received $1,000 by the will of the late Mrs. Eugenia Shumway of Polo, Ill.

Diphtheria Antitoxin in Pennsylvania. According to the report of the Pennsylvania State Department of Health, the mortality of cases of diphtheria treated with free antitoxin was a little more than 7 per cent. in 1908, as compared with a fraction above 11 per cent. in 1907. The results were best in the cases in which the remedy was used early and in large doses.

"Memphis Medical Monthly."—Dr. Richmond McKinney, for twelve years editor of the *Memphis Medical Monthly*, has announced his retirement and the appointment of Dr. J. H. E. Rosamond as his successor in the editorial chair.

"The Yale Medical Journal," in its issue of July, 1908, announces the commencement of a very considerable change in its aims. Affiliation with the State Medical Society of Connecticut has been effected, and the proceedings of the society will hereafter be published in the journal, a copy of which will be sent to each member of the society. The former advisory board assumes direct editorial control of the journal, which will thus become of more general usefulness to the medical profession of Connecticut.

Addition to St. Anthony's Hospital.—An addition, to cost $200,000, is to be made to the hospital of St. Anthony at Padua, Ill. The principal addition will be a five-story fireproof building, 112 by 50 feet.

The New St. James' Hospital, at Pontiac, Ill., built at a cost of about $100,000, was dedicated recently with appropriate ceremonies.

St. John's Guild.—More than a thousand a day has been the average number of mothers and little children carried on the Floating Hospital of St. John's Guild this summer, an increase over last season's average of over 200. In thirty-five trips made 35,470 persons have been taken for a day in the fresh air. The floating hospital trips usually stop with the end of August, but this year on account of the long spell of hot weather the guild is anxious to continue them at least through the first week in September and is appealing for funds. Contributions may be sent to Isaac N. Seligman, treasurer, at 103 Park avenue.

Professional Incomes in Berlin.—Official statistics have been published showing that among 4,000 physicians practising in Berlin 778 have a yearly income below $750, 683 more an income below $1,125, and only a very few get above $3,000.

Dr. C. A. Ewald of Berlin, Editor of the *Berliner klinische Wochenschrift* and a well-known writer on diseases of the digestive tract, has been made an "ordentlicher Honorarprofessor" at the University of Berlin. Dr. Ewald was born in 1845, in Berlin, and entered upon the practice of medicine in 1874. He was at first "Privatdozent," and later, in 1882, was made extraordinary professor at the University of Berlin. He was attending physician at the Berlin City Gynecological Hospital from 1876 to 1886, and since that time has been on the attending staff of the Kaiserin Augusta Hospital.

Dr. Jean Charcot, son of the late Dr. J. M. Charcot, the famous French neurologist, sailed from Havre on August 15, on the *Pourquoi Pas*, for the South Pole. This is his second voyage of discovery in that region, he having led a similar expedition in 1905. After reaching Alexander's Land, M. Charcot plans to continue his cruise in a southwesterly direction, to explore and define the southern limits of the Pacific Ocean and to determine accurately whether or not there is a vast continent extending as far south as the Pole itself.

Dr. B. J. Lloyd of the U. S. Public Health and Marine-Hospital Service has received honorary Ecuadorian citizenship by a special act of the Congress of the Republic, in recognition of his services in connection with the sanitation of Guayaquil. Dr. Lloyd was appointed by the Ecuadorian Government President of the Sanitary Commission and took a prominent part in stamping out the bubonic plague in Guayaquil.

Dr. Reed on the Political Situation.—Dr. C. A. L. Reed, formerly President of the American Medical Association, is reported from Hot Springs, Va., as saying that the medical profession of this country is preponderatingly for Mr. Taft for President of the United States. "On this point," he says, "I know whereof I speak, for I am in touch with the organized medical profession in every county in the United States and consequently have direct means of information." Dr. Reed is a candidate for the U. S. Senatorship, to succeed Senator J. B. Foraker of Ohio.

Dr. Frederick E. Lettice of Schenectady has been appointed prison physician at Sing Sing, to succeed Dr. R. T. Irvine, who recently resigned.

Dr. Hyman Cohen has been appointed chief disinfector of the Chicago Health Department, vice Dr. Charles W. Biehm, deceased.

Esperanto Congress.—Major Paul F. Straub, of the Army Medical Corps, is the delegate of the United States Government to represent this country at the Fourth International Esperanto Congress, held in Dresden from August 16 to 22. The Congress was formally opened on August 17 with an attendance of 1,800 persons. The delegates were welcomed by representatives of King Frederick Augustus of Saxony, and of the Dresden municipality. Dr. Zamenhof, the inventor of the language, made an address on its ideals. The program of the session announced that its close would be celebrated by a performance by the Dresden Royal Opera

Company of Goethe's "Iphigenie auf Tauris" done into Esperanto.

Pasteurized Milk Stations in Newark.—New stations for the distribution of pasteurized milk are being established in Newark by a joint committee representing the Babies' Hospital, the Newark Social Settlement, the Visiting Nurses' Association, and the Bureau of Charities.

Ozone for Hospital use.—A plant for the generation of ozone has just been installed in the Homeopathic Hospital in Pittsburg. This is said to be the second of its kind in the world, the first being in a hospital in Ireland. Great things are expected from the use of ozone in the treatment of colds and other infections of the upper air-passages.

Death of a Centenarian.—Born in Ireland one hundred and two years ago, Mrs. Elizabeth McClelland of Jersey City died on August 9, after a short illness. She had retained all her faculties until a breakdown three weeks before her death, following a mile walk on a hot day. Until she reached the age of 97 she had attended to all her housework. Mrs. McClelland came to this country when twenty years old.

The Mississippi Valley Medical Association will hold its thirty-fourth annual meeting in Louisville, Ky., on October 13, 14, and 15. The oration in surgery will be delivered by Dr. Arthur D. Bevan of Chicago, and will be on "The Surgery of the Kidneys." Dr. George Dock will give the address in medicine, the title being "Tropical Diseases of the Mississippi Valley."

Obituary Notes.—Dr. Lewis E. Wheat died at Philadelphia on August 9. He was graduated from Jefferson Medical College in the class of 1888.

Dr. John Harvey Borden of Tarrytown, N. Y., died suddenly at his home on August 10, aged 35 years. Dr. Borden was graduated from the College of Physicians and Surgeons, New York, in 1903. He was a member of the New York Pathological and Harvey Societies, and visiting physician to the Tarrytown Hospital.

Dr. Benjamin D. Ashton of Travers City, Mich., died on August 6, at the age of 79 years. Dr. Ashton was graduated from the Cleveland Medical College in 1854, and for forty years has practised in Traverse City, retiring from active work in 1902.

Dr. John O'Falvey of Marquette, Mich., a graduate of the Royal College of Physicians at Dublin and a veteran of the Crimean war, died recently at his home, aged 85 years.

Dr. Walter Hurst of Detroit, Mich., died on August 6 at his home, following a stroke of paralysis, aged 52 years. Dr. Hurst was a graduate of Owens College, Manchester, a pupil of Thomas Huxley, and had been in this country four years. He was for a number of years Secretary of the British Medical Association.

Dr. Charles H. Burr, formerly of New York, died on August 13 at his home in South Framingham, Mass., at the age of 53 years. Dr. Burr was graduated from the Harvard Medical School in 1882, and was on the staff of the Manhattan Eye, Ear, and Throat Hospital in this city for many years. He was obliged to relinquish his practice several months ago because of failing health due to kidney disease.

Dr. Albert G. Sprague of Riverpoint, R. I., died on August 2, after an illness extending over several years. He was a veteran of the Civil War, a member of the Rhode Island Medical Society, and for many years was president of the State Board of Health and health officer of Warwick.

LETTERS TO A NEUROLOGIST.

To which are appended brief replies purporting to set forth concisely the nature of the ailments therein described with remarks on their appropriate treatment.

XI. From a Doubting Thomas.

Washington, June 18, 1908.

Dear Doctor:

I have read with interest the "Letters to a Neurologist" that have been appearing in the Medical Record during the past few months, and I am moved to add one more to your collection. It is obvious that you have had considerable experience with the general practitioner, and I say to you that I have had not a little with the neurologist. This letter is not written to cast any aspersions, for I may truthfully say that it has been my experience that, when the neurologist is a practitioner of medicine who has had special training in nervous diseases, he is a most satisfactory consultant. But what I am particularly at a loss to understand—and desire for enlightenment is the object of this letter—is the quality of advice that many of my patients get from neurologists. Take, for instance, a patient seen by me to-day. A man in charge of a small business, a steam laundry, consulted me two years ago, seeking relief from attacks of pain in the legs—rheumatism, he called it—and difficulty in passing water. I couldn't make much out of him, so I suggested that he should go to see a nerve specialist in Baltimore. He did so, and was told that he had locomotor ataxia. He was given a saturated solution of iodide of potassium and told to take thirty drops of it four times a day. He says that he was told that his treatment could be carried out as well at home as there, and that the disease was incurable. However, it might be years before he would be incapacitated. He was warned to keep away from quacks.

This, it seems to me, was like taking a backwoodsman who had never seen a balloon but had heard of it, and who desired to make a journey in one, putting him in the car with something that was thought to be ballast, telling him to throw it out if the balloon did not go up properly, and then cutting the captive rope. You couldn't have any very sanguine expectations that he would come down in Philadelphia or other safe place remote from the starting point. In fact, one could not give reasonable assurance that he would come down at all. The truth of the matter is that the chances would be all in favor that the errant would come a cropper, and that's just what happened to my patient. He went home and took the medicine for a while, and as he didn't seem to be improving, he sought those who had no doubt but that they could cure him. First, he tried a "chiropractitioner" of this city. She rubbed him violently—that is all he knows about her treatment, save that he felt 100 per cent. worse when he came out of her establishment that when he went in. Then he went to a place where he was treated with vibration for three weeks. They didn't claim they could cure him, but they could relieve him. Promises, like piecrusts, one of your correspondents writes, are easily broken. These were of that brand. He was then advised to go to the Hot Springs of Virginia, and there they gave him the douche and hot-blanket treatment. He lost several pounds in weight and an incalculable amount of strength, and returned a weaker but wiser man. He then put himself under osteopathic treatment, which apparently benefited him, but he got discouraged when a particularly severe attack of pain seized him. Now he reads in

the Sunday papers that there is a doctor in New York who cures such diseases as his by treating the deep urethra, and he comes back to me to get my advice about going to see him.

Now, I submit that the neurologist to whom I sent him is to blame, in part at least, for this man's wanderings, and he is, in a measure, responsible for his present condition, which is infinitely worse than when I first saw him. Believe me, this is but one of several cases that have come within my personal knowledge. I can give you details if you desire them. Practically all my patients that have got into the hands of quacks and vicarious physicians have gone *via* the neurologist. I don't say they wouldn't have got there anyway. I content myself with stating the fact. The question I want to ask in this connection is: Is the impression which so many physicians have, that the neurologist seems to be content when he has made the diagnosis, founded in fact? Does he display the same keenness and insight in his search for the cure or amelioration of the disease as he does in detecting it? Is he as resourceful in suggesting means to combat the disease as he is diligent in discovering mo'es of eliciting it? Does not the mental picture which he has of the diseased tissues as he observes them upon the autopsy table blot out the nascent idea that anatomical and functional restitution may be possible, and leave in its place *cui bonum?* Is it not possible, now that tuberculosis is taking its place among curable diseases, that epidemic cerebrospinal meningitis is succumbing to the products of the laboratory, that the cause of syphilis has at last been discovered, that vaccine therapy is giving earnest of great promise, the neurologist takes an unjustifiable and untenable position in pronouncing many diseases of the nervous system incurable, and conforming his conduct to his dictum? Perhaps you do not agree with me that he does so, but I venture to say that such is the opinion of many general practitioners like myself, and I should be glad to hear from you relative to it.

Another point concerning which I seek information: I note that in many of your letters you lay great stress upon the rôle which heredity plays in the causation of nervous diseases. Don't you think heredity is overdone in this respect? I think you will agree with me that it has been the trend of science to show that disease of all kind is due to accident or design. Accident in encountering the various bacterial and protozoal causes of disease, and design in overeating and overdrinking.

You, no doubt, recall that it is not so long ago that the chief cause of tuberculosis was thought to be the inherited diathesis. Yet, what writer on the causation of tuberculosis wastes words on the inheritance of the disease to-day? Then, again, what facts, reliable, trustworthy, and uncontroverted, have we to show that any but a few rare diseases flow directly from our ancestors, and in those is not its occurrence to be construed as a protective effort on the part of Nature, which, Bard and Sage, inspired and profane writer, are unanimous in saying, tolerates no interference?

I appreciate that some nervous diseases, perhaps many, are considered to be distinctly hereditary, but to me the claims put forward regarding many of them do not seem to be entirely legitimate. Oftentimes, when I read a pedigree of nervous diseases, I am in doubt whether they should be regarded as illustrations of heredity, pure and simple. Some of the diseases regarded as hereditary, may, it seems to me, be due to the transmission of a disease germ through the reproductive cells, like pébrine of silkworms and like the inheritance of syphilis. There can be no doubt, it seems, that syphilis is hereditary. Therefore, the spirochætæ must be transmitted through the reproductive cells.

After a considerable number of years devoted to the practise of medicine, I have come to the conclusion that we attach too much importance to heredity. It may be that my observations, which have largely been in family practise, are too few to entitle me to an opinion.

Isn't it true that we are more in the air, as it were, in the treatment of nervous diseases than we are in the treatment of any other class of diseases? When a patient comes to me to be treated for gout, or diabetes, or aortic incompetency, I give him some advice, some instructions how to live, and some prescriptions, and I expect that he will improve or get well, but when a patient comes to me with epilepsy or amyotrophic lateral sclerosis, or tabes, and I treat him in the same way, I expect that he will get worse or never come back. In the latter respect, I am rarely disappointed, I regret to say.

I did not intend to burden you with such a long letter, but I venture to hope that you will deem it worthy of an answer. Believe me,

Yours cordially,

.....

New York, June 20, 1908.

My Dear Doctor:

I am glad to get your letter of the 18th inst., and to have the opportunity to reply to it.

I think I appreciate fully your motive in writing me. Although it may seem at first sight that your animadversions on neurologists are founded in fact, I hope to be able to explain them so that they cannot be construed as condemnatory.

The patient with tabes, whose history you relate, may have been inadequately treated by the consultant to whom you sent him, but you must remember that we have only his uncorroborated testimony. What the doctor said to him may have been quite different from that which he related to you. It seems improbable that anyone familiar with the history of tabes and the change that has taken place in its clinical course during the past twenty-five years should say unqualifiedly to a patient, or to anyone else, that it is incurable. The truth of the matter is that at the end of another generation it is not improbable that tabes will be a curable disease, for there can be no doubt, I think, that at the present time its course is materially influenced by appropriate treatment. The consultant may have erred in not having outlined to him with much precision the course of treatment which he should pursue, the frequency with which he should report to his physician, and the varieties of therapeutic aid which he should endeavor to secure, such as massage, electricity, counterirritation, methodical, purposeful movements, appropriate dietary, proper apportionment of work and relaxation, and the various other adjuvants that have been found useful in the treatment of this disease. He may have thought that the patient's circumstances would not permit him to employ these measures, or he may, unfortunately, be something of a therapeutic pessimist, particularly as he lives in a city in which therapeutic pessimism was a hall mark of good form at one time. Also, he may have thought that these adjuvants were not of sufficient service to make their serious employment justifiable. Of course, if he were of the latter type, I can say nothing in his defense, for the therapeutic nihilist has no justification for existence as a neurologist.

You say that practically all your patients that have come into the hands of quacks and clergymen have gone *via* neurologists. If you will absolve me from rudeness and assure me that your feelings will not be hurt by the expression of my honest conviction in this matter, I shall say to you that the real reason that they find themselves in the hands of quacks at all is that the practitioner to whom the neurologist returned them after making a diagnosis and suggesting a plan of treatment is incapable, from lack of training and serious inclination, to carry out the plan of treatment that is outlined. So little value in the treatment of any disease does the administration of medicine have, save in a few diseases in which it is specific, such as quinine in malaria, mercury in syphilis, thyroid extract in myxedema, and so deeply rooted is the belief that medicines are capable of coping successfully with disease, that it is very difficult for the practitioner who has been trained largely in the treatment of self-limiting diseases to liberate himself from the tyrannical hold that drugs have upon him. When he comes to the treatment of diseases in which restitution of function is largely a matter of metabolism and the regaining of a normal mental state, in other words to a class of diseases in which drugs play comparatively a small rôle, the practitioner does not know what to do. He can tell the patient to eat food that is nutritious and to avoid that which he has found from experience does not agree with him, to avoid fatigue and other debilitating encounter, to conform to the health maxims found in Poor Richard's Almanac, but as a rule he can't show some strong limbed member of the family how to give appropriate massage, he can't put in simple, plain, explicit language the directions for taking tonic baths, he can't outline a course of rhythmic movements for the cure of some distressing tic or habit spasm, nor can he write a dietary and convince the patient of the necessity of complying with every detail of it with the same scrupulous care as he requires them to comply when he is seeking to combat diabetes. In other words, the general practitioner does not take time and expend the energy to familiarize himself with the details of treatment which are not only necessary but essential in the treatment of nervous diseases. To what does the pediatrist of to-day owe his enviable position in the medical profession? To the fact that he has seen the necessity of mastering the details of infant feeding, and carrying them out with an exactness that rivals the martinet. The practitioner who competes with the pediatrist in the care of sick children, presents a sorry spectacle if he is not familiar with the dietetic requirements of the infant at different months of its life, with the details of modified milk, in short, with the whole paraphernalia of the bringing up of infants in the modern way. He finds that it is to his material advantage to acquaint himself with such details. The art of the neurologist is based on a much more intricate and complex comprehension. Yet I must say that I see very little evidence of any desire on the part of the physician to perfect himself in this art. Nevertheless it has been my experience (which I state reluctantly and regretfully) that the practitioner who admits that he knows little or nothing about neurology, displays a willingness to undertake the management of neurological cases. I need not say to you that the result of assuming such responsibility is not always successful. I am of the belief that the general practitioner should treat nervous cases and I have frequently urged this both in my lectures and in public print, but I maintain that before he undertakes to do it, he should give some evidence of his earnestness and good faith, and before we shall get that, I feel convinced that he must entirely change his attitude towards nervous diseases.

Let us go to the foundation of the matter. Are we not all familiar with the physician whose salutation in the presence of a patient suffering from disorder of the nervous system is, "You see I know nothing of nervous diseases"? A thoroughly trained physician is humiliated to confess that he does not recognize the ordinary diseases of the skin, or of the eye, or of the gastrointestinal tract, but the erudite and the mediocre seem to add a trifle to their stature by confessing that the field of nervous diseases is to them absolutely unknown territory. Moreover, it is a territory which apparently they have neither desire nor inclination to explore. In our great country with its hundreds of medical colleges there are very few professors of medicine who feel competent to participate in a discussion in the domain of clinical neurology even. There are comparatively few such incumbents who are willing to admit that they have sufficient training in neurology to make a diagnosis of any obscure nervous disease. These men imbue their students, perhaps not by word of mouth but by example, which is much more potent, with the idea that intimacy with nervous diseases is not of any great importance. The result is that the general practitioner has a feeling that it is not worth while.

The truth of the matter is that the practitioner of medicine who is best fitted to treat chronic diseases, it matters not what organ or system is diseased, is the neurologist, for he is a man who has had training to apprise him of the value of detail. He is a man who has had it impressed upon him that successfully to treat any disease, there must be constantly in the mind's eye of the man who essays to do so not only a picture of the disease but a picture of the process which he desires to initiate and carry through to a successful issue. The training that he has had in the laboratory and at the bedside, necessitating as it does protracted, repeated, and exhaustive examinations of the various constituents of the motor, sensory, secretory, and metabolic mechanism of the body, not to mention the unparalleled opportunities that he has for forming an estimate of the effect which the mind has upon bodily states, fits him preeminently for the treatment of chronic diseases. He has to study with scrupulous care and attention the application of the many agencies that aid anabolism and provoke catabolism. In determining them he must search like a detective and deduce like a philosopher. For in reality these conditions are the basis of every chronic disease. He observes the immeasurable effect which the mind has upon the body and he soon discovers for himself (even granted that he is deaf and insensible to what the past has to say to him upon this score) that hope and faith and confidence and other components of optimism are the most valorous soldiers in fighting diseases. He does not feel impelled to proclaim this knowledge from the housetops, nor to preach it from the pulpit, nor does he lend himself to cults, religious or other, that trade upon credulity of the feebleminded or upon the aboulia of the obsessed. He utilizes his knowledge for the welfare of the sick who entrust themselves to his care. He preaches the gospel of sane living and sound thinking. He believes these are even more important for the sick man than they are for the well man. When a leaking roof allows the water to percolate into the house and destroy plaster and paper and paint, the man who is asked to repair the

house does not go there and pour in a stream of cement hoping it will fill up the crevices here, and block the opening there, and thus make the house fairly habitable. He makes a careful survey of the original lesion, he repairs it as thoroughly as he can in order that no more injury may come through it, and then he proceeds with paperhanging, and mortar, and every other artifice of his craft or of his fellow-craftsmen to repair the damage.

This is what the neurologist does when he undertakes to treat a case of nervous diseases. Take for instance: The new neurologist sees a case of acute anterior poliomyelitis, he may be absolutely certain of the diagnosis, nevertheless he does a lumbar puncture, he has a complete chemical and microscopical examination made of the spinal fluid, of the blood, of the stools, of the urine, and the treatment he gives is suggested in a measure by the information which he gets from such examinations. He then has a very definite idea of that which he wishes to accomplish, viz., to mitigate the intensity of the inflammatory process in the spinal cord, to maintain the nutrition of the muscles whose nerves are diseased at their origin, to prevent deformity. He utilizes drugs which he knows have an effect to cause absorption of inflammatory products, he applies electricity and mild counterirritation to the spine, he massages gently the artrophying muscles, he injects strychnine into them, he wraps the limb in cotton wool and keeps it warm in the physiological position; in other words, he assists the reparative process of the body. He can't furnish new material as can the repairer of the house, but he can so order and arrange the reparative powers of the body that the job shall be well done.

That which he does in the treatment of diseases such as so-called essential paralysis of children is paralleled by his actions in the treatment of the majority of other nervous diseases. There are some diseases which he knows are uninfluenced by treatment of any sort, such as amyotrophic lateral sclerosis, but when called upon to treat these diseases he makes an effort to check their progress and he is constantly hoping to discover some treatment that will influence their course. On the other hand he deals with many diseases which experience has taught him are unamenable to treatment, such as the muscular dystrophies, general paresis, syringomyelia, etc., but I should like to ask you by way of answer to the latter part of your question whether you ever encountered a neurologist who did not attempt to treat these diseases with as much precision and orderliness, and I may add with as much hope of success, as the internist treats aplastic anemia, cirrhosis of the liver, or emphysema? I do not recall that any one claims that these latter diseases are susceptible of cure.

I think that you will find, if the matter is inquired into in good faith, that the neurologist is not the radiator of gloom that your letter would seem to imply. The reputation of the neurologist as a pessimist is like that of the stage Irishman, a figment of the imagination which custom has immortalized.

In reply to the second interrogation, concerning the importance attributed to heredity in the causation of nervous diseases, I confess that a suspicion has been filtering through my mind for some time that perhaps we were attaching a greater importance to it than it deserved. At least I agree with you so far as to say that the hereditary diseases, using the word in the sense of the naturalist, are few, but that many individuals get something from their heredity which facilitates the development of nervous and mental diseases cannot be denied.

One reason why heredity seems of such vast importance to me, and perhaps not to you, is that we may attach a different significance to the word. When I use the word heredity, I do not mean to imply that it is a force or a power making for continuity or for persistence of character, but the genetic relation between successive generations. All that the organism is or has to start with is its heritage. Its inborn potentialities it owes to its parents and ancestors. We physicians practically pay no heed whatsoever to this, in our interpretation and search for the cause of the disease, while on the other hand we devote the greatest attention to environment, which includes food, climate, housing, and scenery, and to function, which includes exercise, education, occupation, etc., in other words to influences that act upon an organization whose fundamental nature is determined by its heredity. It is natural that we should give more attention to the latter than to the former because in so doing we witness the fruits of our labor. Breeders and cultivators who have profited to any incalculable extent by discovering and applying the laws of inheritance, are able to point to results, but even though we were in relatively the same position as they are concerning these laws we should be unable to apply them.

My own belief is that we are on the threshold of making most important discoveries in the field of heredity from the application to the problems presented by disease of the principles laid down half a century ago by the Austrian monk, Gregor Mendel. I have no intention to say to you here, what the signs are that indicate such discovery. Certain it is that we were making little headway in the interpretation of nervous diseases on the hereditary basis along the lines laid down by Darwin, Wallace or Weismann but in the light of Mendelian heredity it is quite probable that many of them will yield the secret of their existence. Although consideration of the facts of heredity as they have been determined by experimentation upon the edible pea, and empirically by physicians in the study of disease and abnormality, does not tend to promote cheerfulness, neither does the fate of man unless one is deeply imbued with the religious spirit. Hand in hand with the advance made by preventive medicine, which is now used synonymously with the prevention of microbic diseases, should go progress in the science of generative or procreative development. I realize fully that we are not sufficiently advanced in civilization to enter fearlessly the domain of eugenics, but I believe that the day is not far distant when not only our profession will deal with it but the State as well.

The concluding paragraph of your letter discusses a phase of the subject which I should under other circumstances be very glad to take up, but this reply has already taken on such length that I can not permit myself to do it here.

Yours very sincerely,

.....

Reappearance of Diphtheria in Children Previously Treated by Antitoxic Serum.—Barbier records three cases of children previously treated for diphtheria by antitoxic serum, or injected for prophylactic purposes, in whom the appearance of another exanthem, measles, caused a recurrence of the diphtheritic membrane in the throat or elsewhere. Scarlatina may have the same effect. The evolution of the disease is then graver and the prognosis worse than in the first attack. A fresh injection of the serum should be made in these cases. The recurrence will often occur during the three weeks in which the child is supposed to be immunized.—*Journal de Médecine de Paris.*

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE BRITISH MEDICAL MEETING—ASSOCIATION FOR DESTRUCTION OF VERMIN—RELATION OF HUMAN AND ANIMAL DISEASES—PROPOSED LEGISLATION—ANTIMALARIAL FISH—THE POLYCLINIC—DEATH OF SIR T. STEVENSON.

LONDON, July 31, 1908.

THIS is the week of the British Medical Association, and, to a certain extent, the center of interest shifts to Sheffield, where the meeting is held this year. But London is by no means deserted by the doctors. In fact, there are about twice as many here as are wanted. A goodly number have gone to Sheffield—the officials, of course, were present at first for the general and formal business. Many others have only taken a day or two there, for the section in which they are interested or are to take a part. Still others go for one, two, or three days, and thence start for their holidays. A few have returned, some well satisfied and the rest disappointed. But none I have seen display much interest in the proceedings. As you have your own reporters there you will no doubt receive details of the scientific work.

At present there is much more talk about the "Association for the Destruction of Vermin," which held its first important meeting last week at the house of the Royal Society of Medicine. The London School of Tropical Medicine, to which practically the new association owes its existence, appeared in full strength to support their colleague, Dr. Sambon, who opened the discussion with a learned paper, which concerns many points connected with the relation of the diseases of animals to those of man. I say animals as a wider term than vermin, for there seems a tendency among our tropical friends to extend the latter word to any creature noxious to man by spreading disease. This seems too much of an "etymological inexactitude," and people will hardly agree to call birds vermin.

Dr. Sambon, you perhaps know, investigated the grouse disease and found five new microbes. He has since been engaged investigating the diseases of pheasants and other birds, and has made some discoveries in connection with them which seem highly suggestive. Such, for instance, as the prevalence of pneumonia and diphtheria in birds, especially those of migratory habits, and the coincidence of outbreaks among the inhabitants of certain localities on the arrival of flocks. This seems on a par with the migratory habits of rats, which are now recognized as carriers of plague—a revival of the view of the ancient Greeks and others. The terrible ravages of plague in India, where, it is said, above a million persons perished from it in the year, gives the utmost importance to this view, and accounts for the unusual vigor of the new society in the attempt to destroy these vermin. In the docks and warehouses on the Thames a regular campaign has been inaugurated, with the assistance of the port sanitary authority 550,000 rats have been slaughtered, and the war is still being vigorously prosecuted. An exhibition of traps and other rat-destroying appliances is also to be held. Moreover, the Society for the Destruction of Vermin is drafting a bill, with the hope of its passing through Parliament, to confer on local authorities extensive powers to enable them to exterminate the rodents. Several members of Parliament are giving their assistance. But, as I have shown above, the rat is not the only vermin that the society wages war on. A subcommittee has undertaken a raid on bugs and other nocturnal pests. The house fly is also to be attacked, and this is just the season for it.

A somewhat cognate subject—malaria—is receiving an unusual illustration at the Zoological Gardens, to which Mr. C. Kenrick Gibbons has presented a number of the small fresh-water fish from Barbados, where they are called "millions," and are credited with the power of preventing malaria. People visiting the gardens are pleased to see them in a tark in the tortoise house and to hear that enormous numbers are found in the fresh-water pools of Barbados. These fish (*Girardinus poecilloides*) are very voracious, and consume large numbers of the larvæ of mosquitos, so that their reputation of preventing or at any rate restricting the spread of malaria may not be altogether undeserved. The males are about one-half inch long, with brilliant iridescent coloring and large black spots on the sides. The females are less brilliantly colored, but are larger. It is proposed to introduce them into malarious countries.

An appeal is being made for help for the Polyclinic, on educational and charitable grounds. As to the first, because it provides postgraduate instruction on nominal terms (£1-1-0 per annum); as to the second, that its consultation department affords patients who cannot pay adequate fees the chance of consulting the most eminent specialists. On this point I feel some doubt about the charity involved. Most of these patients could pay a moderate fee, and that might be accepted by one who had not attained the foremost position. For example, why should not the assistant surgeon to a great hospital accept a fee which would not be taken by the full surgeon? Or the young physician, who has taken a house near the King's adviser, might very well be permitted these lesser fees, and perhaps his advice would be quite as good.

Mr. Jonathan Hutchinson has received from the Royal College of Surgeons a letter signed by the president and vice-president, congratulating him on having attained his eightieth year.

Sir Thos. Stevenson died on Monday of heart failure, aged 70. He had been ill for some time, but he was expected to recover. He was a Guy's student, took M.D. Lond. with scholarship in forensic mediciné and midwifery. He was lecturer on chemistry at Guy's from 1870 to 1898, on forensic medicine from 1878. He was F.R.C.P., a past president of the Society of Medical Officers of Health, of the Institute of Chemistry, and of the Society of Public Analysts. He had served as examiner in sanitary science at the University of Cambridge, in forensic medicine at the London and Victoria Universities, and in public health at the Conjoint Board. He edited the later editions of Taylor's "Medical Jurisprudence," and contributed to the journals and societies on his specialty. He was knighted in 1904. He had a full career as medical jurist and expert in toxicology, for he was the adviser of the home office in those matters, and you will remember that he was consequently prominent in all the most famous trials since the death of his predecessor, Dr. Alfred Taylor.

ORIGINALITY AND PRIORITY IN MODERN CYSTOSCOPES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the MEDICAL RECORD of February 29, 1908, and in the *New York Medical Journal* of April 11, 1908, Dr. F. Tilden Brown of New York is quoted as presenting a paper on "Ureteral Catheterization" before the meeting of the Medical Association of the Greater City of New York, held January 20, 1908. In this paper the essayist makes certain well-defined claims to originality and priority with respect to his instruments, and also claims that his originality has been trenched on. The allegations are so worded as to leave no doubt that I am the one accused, and also, leave no doubt as to the necessity of a reply, which is herewith presented.

In order that Dr. Brown's position may be correctly stated, this report is quoted, as follows: "Dr. Brown's

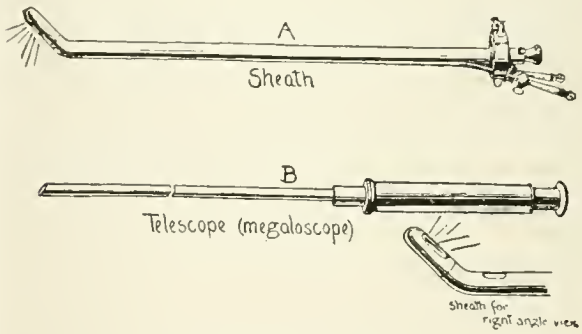

FIG. 1.—Boisseau du Rocher, 1889.

remarks were directed more particularly to instruments and methods with which he himself had to do, and were supplemented by wall drawings and photographs to demonstrate the various developmental forms, since 1900, of his original 'composite cystoscope,' the identical instrument which a St. Louis cystoscopist had recently appropriated, and had been presenting as his own 'universal cystoscope.' This composite cystoscope, made by the Wappler Co. of New York, was a vastly more useful instrument than its immediate predecessor, the author's double-catheter direct-vision cystoscope, which Leiter of Vienna made for him in 1898, and which was the first telescopic cystoscope, of any form, to provide for two catheters and effect synchronous catheterism of the ureters. But this Vienna instrument had no reserve channels for irrigation. It was with

the end in view of finding a way to add such irrigation channels to the already practicable double-catheter direct-vision cystoscope, while, at the same time, not increasing the circumference of the shaft beyond 24 French, that the Brown-Wappler efforts were first directed, in 1900. It should be here added that the

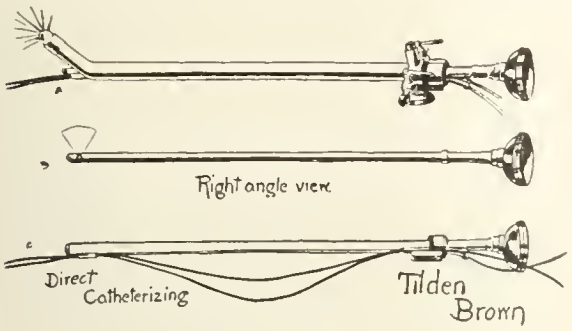

Fig. 2.—Tilden Brown, 1901–6.

speaker's first double-catheter instrument was but a modification of the then existing Brenner single cystoscope, whereas his subsequent instruments involved a wholly novel departure from all the preexisting types. The first essential change lay in getting rid of the old-time terminal window at the vesical end of the sheath, which was followed by the use of different kinds of interchangeable telescopic tubes for the same common sheath. Up to the present time its development on this basis had resulted in giving us at least three complete cystoscopes for different purposes, adjustable in one sheath."

So far from being the originator of the sheath-and-multiple-telescope feature in cystoscopes, or of the double-barreled catheterizing channels, Dr. Brown was antedated ten or eleven years in the presentation of these features. In 1889 Boisseau du Rocher described by both text and illustration* his early models (Fig. 1) of cystoscopes, which embraced the following several objects: (1) Direct view for inspection; (2) indirect view for inspection; (3) irrigation of bladder, either through the two catheter tubes during manipulation or through the sheath when obturator and telescope were not in place; and finally (4) double-barrel catheter channels for synchronous catheterization of both ureters.

As settling the priority of the double catheter channel feature, one has but to read the words of Boisseau in connection with his illustrations, as follows: "The little tubes [running in the lower wall of the sheath] have two different purposes. They serve as conductors for the ureter catheters. Nothing is simpler, with the orifice of the ureter in sight and the catheter in place, than to guide the latter and insert it in the ureter to the depth desired. Finally, being controlled and independent, every facility is furnished for catheterizing the two ureters without the necessity of withdrawing the instrument or disengaging the first catheter." Practical success in the use of this instrument was attested by Poirier.†

Following Boisseau's epoch-maing contribution of

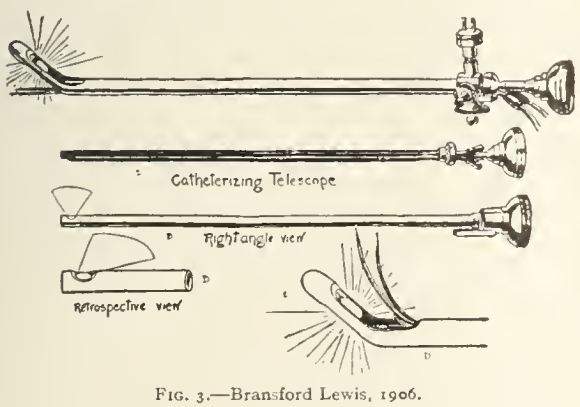

Fig. 3.—Bransford Lewis, 1906.

1889, a number of other cystoscopists adopted his sheath-and-telescope plan in the construction of cystoscopes, according to their individual ideas, among whom may be mentioned Güterbock, 1895; Fenwick, 1896; Nitze (evacuation cystoscope), 1897; Albarran, 1897; Koch-Preston, 1898; Lang, 1899; Schlagentweit (evacuating cystoscope), 1899; Kollman, 1900; Wassidlo, 1900, and the air-cystoscope of the writer, 1900. All of these antedated Brown's composite of 1901 in the sheath-and-telescope feature, whereas his double catheter channel feature of 1899 was antedated, as mentioned, by just ten years, by Boisseau.

The plan Brown adopted in his composite of 1901 of placing the lamp on the tip of the beak originated with Dittel in 1880, and was later used by him by placing Edison's incandescent lamp in that position on a Nitze cystoscope.

So far from being "a wholly novel departure from all preexisting types," as he claims, Brown's composite presented no feature of intrinsic originality or priority; for that reason, if for no other, I could not trench on him in the production of my universal cystoscope of 1906. Moreover, at the presentation of the instrument* the following definite disclaimer of originality was made use of: "In presenting the next candidate for cystoscopic favor, I do so with the full realization that there is no yawning vacancy in the cystoscopic field; that 'there are others' already in the field; also that it is difficult to find anything really new and original, at this date, in the cystoscopic world; that most of the supposed 'new' features are simply modified settings or assemblings of features already made use of. It is not desired to lay any especial claim to priority or originality in this instrument; utility is its basic principle."

As to whether my universal is the "identical instrument of Dr. Brown's," reference to the respective illustrations of the instruments (Figs. 2 and 3) will readily determine. The differences are so evident that it is scarcely worth while to bring argument to bear on the subject or mention the various and definite differences between them that existed when the universal was presented, in 1906. The accompanying illustration of Brown's composite (Fig. 2) is reproduced from his own writing.† If the later models of the Brown instrument (1907-1908) have grown to so closely resemble mine as to substantiate the statement of practical identity of the two instruments, it is not because of changes in mine, which has retained its essential individual features of double fenestration of the beak, inversion of lamp, complete double-catheter grooves, instead of closed channels, etc., from the first. Whereas I am informed that these features have been adopted for the Brown instrument since the beginning of 1907, the year after my universal was submitted.

A MEXICAN LABOR.

To the Editor of the Medical Record:

Sir:—From time to time the peculiar methods of midwives in various places are brought to the attention of the medical world, and I venture to think the customary technique in vogue among the Peons of Northern Mexico would be of interest. The Peon, or working class, of Northern Mexico is of nearly pure Indian descent and is born and raised in dirt. Imagine a rough, unceiled hut, twenty by fourteen feet, wherein a family of eight people are living with three pigs, a few goats and chickens, two dogs, and several cats. The house stands in the full glare of the sun, the doors and windows are tightly closed to keep out the gaze of the curious as well as the breeze. Here, in one corner, screened off by a few dirty old blankets, I found the woman in confinement. The bed was of two old blankets, a couple of bran sacks and a goat skin arranged on the floor, the goat skin being on top, fur side down, taking the place of our rubber sheets. The patient was a well-built, well-developed girl of eighteen, a primipara. It was because of this the mother insisted that I be present in case of accident, but not to do any of the actual work. The patient was wearing her usual house costume, consisting of an old, dirty black skirt and a waist that was dirty beyond description. There were two midwives in attendance, one being stationed behind, holding the patient's hips between her knees, both arms about the waist just above the uterus, a sort of human chair. As each pain came she hugged with all her force, which was considerable. Hanging in front of the patient was a rope of old clothes, bags, and towels,

*Am. Urolog. Ass'n, at Boston; *Am. Jl. of Urol.*, Dec., 1906.

†Bellevue Hosp. Reports, 1905.

up which the patient drew herself when the pains began. The chief midwife was in front, about the dirtiest, most ill-visaged bundle of humanity one would ever meet. She was squatted on her heels, with a hand on either of the patient's hips under the skirt.

Dilatation was not quite complete on my arrival, but in less than a half hour it reached the complete stage, the bag of waters emptied and things began to get lively. The husband, mother, and father were called and by the united aid of the family the child was born. As each pain began the patient started climbing the rope, dragging the posterior midwife up with her until they were nearly erect, the patient resting on the toes, the knees being flexed and widely separated. In this position the husband, mother, and father supported her, being arranged in the order named from above downward; the midwife in front shook and shouted, swaying the patient from side to side, forward and back, working so earnestly that the whole house trembled. Toward the last the patient thrust her fingers into her mouth until she gagged, repeating the operation until her hand was tired, when the husband took up the work. Between them there was kept up a continuous series of gagging until the child was born. After one long, hard pain the head popped out of the vulva like a pea being shucked under pressure, even making a slight pop, a deep breath was taken by all, then one more gag and the child slipped into the hands of the midwife, the woman was allowed to slip to the floor, while the cord was being tied and cut. The cord tie was a bit of string, which the midwife had laid on the floor in easy reach, along with the family scissors, the latter being used to cut the cord after being tied. Without moving the child from between the mother's thighs they had her climb up the rope once more, and after a couple of shakes and a gentle pull on the cord the membranes came away. A folded sheet, which had been loosely worn about the waist, was drawn as tightly as the father and husband could draw it, and then tied. The mother brought a good, generous bit of lard on the ends of the fingers, which was transferred to the midwife, who daubed it on the stump of the cord, and the third stage was completed. All with one accord lighted shuck cigarettes, the mother bringing a lighted one for the patient. The four women prayed in silence for a few moments, then a short prayer of thanks was offered, the patient kissed the picture of the Santa Niña, after which she was lifted to a dry blanket, without removing the dirty skirt. Here the posterior midwife crouched, holding the patient's head in her lap, crooning to her until she slept. The baby was at once put into the wash trough and given a good scrub with soap and water, after which it was dried, rolled in an old skirt, and given to the patient, and one more childbirth had been completed. I examined the woman for laceration, but much to my surprise found none. She and the baby were under my care for a couple of weeks and there were no complications aside from constipation on the mother's part and a slight conjunctivitis on the part of the baby, both of which yielded very promptly to treatment. The woman insisted on getting up on the fourth day, but involution seems to have gone on naturally without any harm, and at present the woman is doing her work and nursing the child, in the best of health as far as one can judge.

This is but an average case, no worse than half the labor cases of the camp. Still, with the average of six or seven full-term children each, the proportion of healthy old women is considerably greater than of the men, which only shows a little of what woman was born to undergo.

N. B., M.D.

Hondo, Coahuila, Mexico.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 6, 1908.

Some Aspects of Gonorrhea.—Frederick Forchheimer has made some investigations to determine the truth of the statements which have been made, in this country as well as abroad, by men and women who are interested in the suppression of venereal diseases. Whenever his figures have shown anything it is always that the propagandists have greatly overestimated the frequency and complications and the dangers of gonorrhea. This has been notably the case with specialists in genitourinary diseases in the male and in the female. Many who have written have been satisfied with the old figures of Ricord (80 per cent. of all males have had gonorrhea), which, combined with the views of Noeggerath, would make it appear that very few men and women could escape having gonorrhea. If to this there are added the remarkable mathematical gyrations of Blaschko, it is little wonder that the layman becomes an antigonorrheic howling dervish. That there is much damage done by gonorrhea is abundantly shown by all statistics; therefore, it is a righteous cause to fight for its reduction. But no righteous cause is aided by such lurid statements as have been made in connection with gonorrhea. He recapitulates the results of his studies as follows: The morbidity of gonorrhea is diminishing; the American army and navy are exceptions to this rule; the present mathematical methods of deducing incidence of gonorrhea in all men from morbidity lead to fallacious results; 54.1 per cent of all males have gonorrhea during their lifetime; we have not sufficient knowledge of the facts to state how many women have had gonorrhea during their lifetime; the small number of his cases of sterility does not justify any positive conclusion; prevention of conception is the cause of "one-child sterility" in the majority of instances.

The Tonsils and Their Relation to the General Health.—Charles P. Sylvester, after enumerating some of the anatomical changes produced by hypertrophy of the lymphoid ring, treats of a class of diseases originating through diseased lymphoid tissue of the nasopharynx, those of bacterial origin. The most important is acute rheumatic fever. This disease too often follows tonsilitis to be a mere coincidence. According to St. Clair Thompson, from 30 per cent. to 80 per cent. of all attacks of this infection begins with tonsilitis. Another infection, the germ of which is probably closely allied to that of acute rheumatic fever and found to begin in the tonsils (and probably only so), is erythema nodosum. Another important germ disease having its headquarters in one of the three tonsils is tuberculosis. Tuberculous meningitis has more than once been demonstrated to have had its birth in the pharyngeal tonsil, as also has tuberculosis of the middle ear. The severe and fatal cases of acute streptococcus infection beginning in the tonsils are not easily forgotten. Staphyloccus and pneumococcus infections from the tonsils begin also with extremely high temperature and rapid prostration. Fourteen cases of phlegmonous appendicitis associated with or preceded by acute tonsilitis, with post mortem findings in all, are reported by Professor Kretz. Deaths from acute nephritis in children following infection of the kidney from the tonsils have recently been reported. Retropharyngeal abscess is another form of bacterial invasion often secondary to diseased lymphoid tissue in the nasopharynx.

New York Medical Journal, August 8, 1908.

The Tonsil from an Evolutionary Point of View.—Jonathan Wright refers to the recent work of Brieger and Görke, who regard the pharyngeal tonsil as an organ which protects childhood. They seem to find sufficient evidence to warrant them in the belief that in its hypertrophied condition it is a more efficient protection against the entrance of the unknown germs of the diseases of childhood than when it retains its normal dimensions. The tonsil is a definite organ; it is the most highly developed of all the lymph glands. It is situated at the gateway of nourishment and disease; it is not only at the beginning of the hollow tubes of respiration and nutrition, but it is the first of the internal filters which lie across the bypath from the surface of the vena cava, traversed by the agents of infection. Change in the habits of man brought about by the forces of civilization may be supposed to increase the frequency of tonsilar enlargement, and it certainly increases the amount of bacteria-laden dust. The absorption of these from the pits on the surface of tonsils where drainage and inspiration have carried them, where they have lodged from passing food, is increased, and the inner organs of defense make a larger demand on the outer organs of defense for protection. The clue to a connection which may exist between the hypertrophy and the efficiency of the organ as a bacterial filter possibly may be found in the observation that the small, submerged tonsil is a tonsil of infection, and the large discrete tonsil is the tonsil of health. He does not wish positively to assert that the enlargements of the tonsils are always a protective physiological act of the organism. Neither does he wish to deny that they are frequently, or even usually in adolescence, a menace solely when diseased. Whatever may be the conclusions as to their marked enlargement, the knowledge derived from certain sources and the experimental evidence unite in pointing to the function of the tonsils as one of defense against infection.

Real Conservatism in the Treatment of the Prostate.—G. Morgan Muren says that in the many papers upon senile hypertrophy of the prostate gland, two points must be apparent to the careful student, first, the writer's remarkably good results, particularly as regards mortality, and, second, the cases reported are almost always "selected." He is positively in favor of the removal of the gland whenever the patient's condition justifies the risk. Personally he has operated upon nearly one hundred cases. In a number of these cases, where great infirmity, crippled kidneys and heart contraindicate the immediate removal of the gland, the "two-stage" operation may be well borne. By this is meant the preliminary drainage of the bladder, and later, when the patient has sufficiently improved, the complete removal of the gland. This preliminary drainage affords immediate relief in many cases. Until recently it has been his practice to drain these cases by the perineal route, and later to remove the gland the same way. Recently he has been draining suprapubically, as it seems to be a more rapid method; the abdominal route disturbs the patient less, and if later there is not sufficient improvement to warrant prostatectomy, the suprapubic fistula may be made permanent. There are several classes of cases in which there is every reason not to attack the prostate. An old, broken-down prostatic who has had little or no treatment, after a week or ten days' careful attention, may show such improvement as to be fit for operation. There is a large number, however, so fragile and worn out that any attempt to remove the gland must prove fatal. In these cases he believes permanent suprapubic drainage is the treatment indicated. Preference is given to the suprapubic method of drainage, as there is less subsequent dribbling than by the perineal, less discomfort from the tube or obturator, no added irritation to the inflamed vesical neck, and the interior of the bladder can be explored at the time of operation.

Acute Anterior Poliomyelitis in the Adult.—LaSalle Archambault knows of no commoner organic affection of the spinal cord in infancy and early childhood; but in the adult poliomyelitis anterior acuta is rare. He reports a perfectly typical case of infantile paralysis in a man who has reached his fortieth year. There was a widespread atrophic motor paralysis involving all four extremities. So far as he has been able to ascertain, there is no case on record of poliomyelitis in the adult in which the affection appeared later than the thirty-third year.

Journal of the American Medical Association, August 8, 1908.

Frontal Sinus Operation.—J. C. Beck describes and illustrates a method of opening the frontal sinus by first determining its limits by a skiagram, making a tracing of the same on celluloid, applying this tracing to the exposed bone surface and cutting the osteoplastic flap on its lines. The celluloid tracing can be sterilized in bichloride of mercury and alcohol for use in the operation. The bone flap, after division of the periosteum, is cut through with a chisel, except at the base over the superorbital borders and root of the nose where the periosteum is left intact. There the bone is carefully divided with a Gigli saw from the inside after the bone flap cut away above has been slightly pried out, great care being taken not to injure the periosteum. After eradication of diseased mucous membrane (without curetting) and the anterior ethmoid cells, and enlarging the natural opening, a wick drain in a rubber tube is passed down into the nose, the bone flap replaced, and the skin flap closed. The advantages claimed for the method are the ascertaining of the exact limits of the sinus before cutting the bone flap, and the prevention of the flap falling in by the securing of a firm hinge at the base, and its natural upper marginal bevel, where the anterior and posterior tables join. The operation, he says, is not a radical, but a conservative one, and if it fails the radical operation of taking away the bony flap can be done under local anesthesia. The gauze he removes the day after operating and the rubber tube is replaced the third to the fifth day by a silver filagree or gold tube.

A Cerebellar Diagnostic Symptom.—A. Gordon calls attention to a special symptom observed by him in six cases of cerebellar tumor. Four of the cases came to autopsy which verified the diagnosis. In the other two purely clinical cases the symptoms were typical. The phenomenon in question is the forced deviation of the head to the side opposite the lesion, together with great increase of vertigo and headache when the head is turned forcibly to the other side. He considers the phenomenon of diagnostic value. It does not occur always at the same period of the disease, a fact that is not explainable any more than the appearance of the symptom itself.

Poker-back (Spondylose Rhizomelique).—J. W. Rhein reports a case of this affection in a man aged 64, with complete spinal ankylosis and partial ankylosis of the shoulder, hip, and knee joints. The patient succumbed to general tuberculosis, which developed two months before death. The pathological findings in the nervous system, etc., were slight degeneration of some of the anterior and posterior spinal roots, slight peripheral neuritis, and degenerated muscles in the plantar region of the foot. Rhein holds that these were more probably the results of the bone lesions than their cause and believes, with Leri, that certainly not all these cases have a nervous origin. The relationship of arthritis deformans to these cases is, he thinks, remote.

Compensatory Diarrheas.—H. Stern defines the term "compensatory diarrhea" as "a phenomenon of varying degree and duration apt to ensue and return with more or less frequency in the course of systemic deterioration, and characterized by the diarrheal discharge of incompletely or perversely catabolized substances, or by that of catabolic products normally excreted by other emunctories." He recognizes three types: First, diarrheas occurring with deficient or perverse catabolic processes. Second, diarrheas resulting from functional or structural disease of certain excretory organs. Third, diarrheas occurring during the period of physiological systemic decline. Each of these he considers in detail. Of the first type, among others, are the specific diarrheas of gout, exophthalmic goiter, Addison's disease, and diabetes. In gout constipation is the rule, but it is not uncommon in so-called irregular or retrocedent forms of the disease for an attack to be aborted, or even serious internal complications prevented, by a succession of free bowel discharges carrying off the toxic accumulations. The peculiar diarrheal attacks in exophthalmic goiter, like the excessive activity of the sweat glands, must be regarded as compensatory, and when confined in proper compensatory limits are nearly always followed by temporary improvement. The same is true of one form of diarrhea in Addison's disease; the other type occurring near the end and colliquative in character, is dependent on typical anatomic changes in the intestine. Diarrhea is common in diabetes, where it may be a symptom of the underlying pathological condition. It is indisputable that sometimes a compensatory diabetic diarrhea originates in the small intestines, that by its agency sugar may be excreted, and that during its presence and for some time afterward the intensity of the glycosuria may be markedly lessened or even disappear. Of the second type of compensatory diarrheas Stern mentions only those following severe burns and those concomitant with impaired or suppressed renal function from other causes. Uremic diarrhea is the best known of all compensatory diarrheas, and when occurring without ulcerative changes there can be no doubt as to its compensatory nature. The diarrhea of systemic decline belongs largely to the two above classes, but since it is not as much the sign of disorder of any one organ or function, but of the general decline of all, it is proper to include it in a class by itself. Women are more subject to this type than men, and the cessation of the menses seems to favor it. Old people who perspire rarely are subject to chronic diarrheas, and lessened pulmonary exhalation in the aged is compensated for through the bowels, which seem to retain their physiological efficiency longer than other organs. The intestinal tract is the most efficient regulator of the shortcomings and disturbances in the economy of the aged. An attack of compensatory diarrhea generally indicates that there is no immediate danger to life, and that their frequent occurrence is sometimes a means of rendering life more comfortable is a fact not generally recognized by clinicians, who are apt to institute measures of suppression in all cases. Stern reports a case illustrating this fact. As long as a diarrheal process continues to compensate efficiently for loss of function of the skin, lungs, kidneys, and the organs of internal secretion, there is little immediate danger so far as life is concerned, and the suppression of the discharges may cause grave symptoms and danger. A true compensatory diarrhea should not be interfered with unless there is evidence that the local intestinal irritation and hyperemia unduly prolong the process. Local measures, rest in bed, heat to the abdomen, high rectal or colonic flushings with normal salt solution, and attention to diet are all that is needed in ordinary cases. The diarrhea being symptomatic of insufficient excretion, points toward what treatment is needed for stimulation of the catabolic processes and elimination.

The Lancet, August 1, 1908.

Some Blood Changes in Ankylostomiasis.—A. Hocart Brehaut says that the anemia in cases of ankytosomiasis is due to the presence of a toxin, and it appears probable that the eosinophilia is, in a way, a measure of the amount of toxins circulating in the blood. While in Egypt he made a number of differential counts on adult natives who were suffering from the disease. An analysis of these counts shows that the average percentage of eosinophiles is small compared to the European percentages, and also that there is none of those high eosinophilic counts which have so frequently been described. The average percentage was only 10 per cent. He attempts to explain this by stating that the poorer Egyptians suffer from old-standing bilharziosis, and this is known to be associated with eosinophilia. It appears possible, and in fact probable, that they are in a state of tolerance to toxins of a certain nature.

A Note on the Treatment of Erysipelas.—H. Tyrell Gray dismisses the local treatment of this disease by saying that the infected part should be kept dry by dusting with powder; calomel, zinc oxide, and starch in equal parts were used. The constitutional treatment may be medical only, or combined with vaccination or the use of sera. He favors the use of Metchnikoff's serum in this disease, especially when combined with the use of quinine, stimulants, etc. In the six cases he reports the dose of the serum was from forty to fifty minims.

An Unusual Fracture of the Clavicle.—J. W. Rob reports the case of a medical man who fractured his clavicle during a game of football. The right clavicle was fractured straight across the middle. The inner fragment was about half an inch higher than the outer and slightly in front. Between these two fragments was a third fragment, the upper end of which was square and about three-eighths of an inch across. This fragment projected upwards above the outer fragment about a quarter of an inch. It was freely movable within limits. This case was of interest because, first, the bone was not broken at the junction of the outer and middle thirds, as is usually the case when the violence is indirect. Second, the fracture was not oblique, as is usually the case when the violence is indirect. Third, injury to the brachial plexus or subclavian vessels is more often due to fractures of the clavicle by direct than by indirect violence. There was pressure on the inner cord of the brachial plexus, but there was no obstruction to the return circulation from the arm.

British Medical Journal, August 1, 1908.

Idiopathic Dilatation of the Colon.—M. Feldman says that the great rarity of true congenital dilatation of the sigmoid flexure of the colon is shown by the fact that out of 16,000 post mortem examinations made at Guy's Hospital, only one such case was discovered. He reports a case in which the important symptoms were constipation, distension, and relief of both by means of a finger in the rectum, or on the part of the patient himself by putting himself in a certain position. This last sign would seem to show that there is some kind of valve mechanism at work, although none has been found post mortem. This disease is more frequent in boys than in girls. Most of the cases end fatally before the age of twelve. The best treatment is colotomy above the dilated part, so as to give the affected part a rest. This treatment has been followed by good results. Unfortunately it is seldom that a correct diagnosis is made in time.

Two Consecutive Cases of Strangulated Hernia in the Female.—Horace Brown reports these cases, which were interesting because (1) inguinal hernia in the female is rare; (2) femoral hernia was diagnosed by a surgeon of great experience; he also thought it to be a femoral hernia which has pursued its usually upward course towards Poupart's ligament after escaping from the saphenous opening; (3) the fact that healing by first intention took place under the circumstances. In one of the cases the hernia must have existed for years. From the appearance of the appendix in the sac, it seemed to have occupied this resting place for some time; the walls of the sac were permanently indented by the nodosities on the appendix.

Consumption and Ozonated Air.—John A. Mackenzie has treated two patients with ozone; they were suffering from pulmonary phthisis in an advanced stage. The patients felt better while under this treatment; the dyspnea was relieved, the fever and night sweats became less, the coughing and expectoration were less, the pulse became slower, the arterial tension was improved; whenever the production of ozone ceased they complained of feeling worse, and the symtoms became aggravated. All danger of infection to the members of the household is obviated by the germicidal action of the ozone.

Berliner klinische Wochenschrift, July 27, 1908.

Antiferment Treatment of Cancer.—Hofbauer says that the fertilized ovum forms the best analogy to the cells of a carcinoma showing the same characteristics of progressive and persistent growth, destruction of the tissues of the parental organisms at the point of contact, and general parasite-like activity. This activity of the ovum is brought about by the effect of the entrance of a spermatozoon and the latter's influence, in the light of most recent research, rests upon the ferments it contains or produces after contact with the ovum, thus activating the cells of the latter. Hofbauer thinks that the cells of cancer are likewise activated by some similar ferments, and therefore antiferment treatment is quite logical. There are many substances which have an inhibitory effect upon the action of ferments, and of these Hofbauer has experimented with atoxyl, quinine, horse serum, cholesterin, and others, using them individually or in various combinations. Twenty cases of cancer, mostly in the inoperable stage, have been treated with these substances, injections being made in the neighborhood of the tumors. In general a uniform diminution in size of the tumors has been noted, so that the fact of a special influence of these injections upon tumor tissues is beyond any doubt. In no case, of course, recovery from the malignant disease has been effected; moreover, the effects being present only with the use of local injections, tumors inaccessible to such treatment are excluded from the list of those in which the new treatment may be tried.

Munchener medizinische Wochenschrift, July 28, 1908.

Milk Diet in Obesity.—Moritz uses exclusive milk diet in the treatment of obesity. The quantity of milk allowed the patients ranges from 1 1-4 to 2 1-2 liters in twenty-four hours, administered in five portions. Boiled milk is preferable to raw milk. It may be drunk cold or warm, as preferred by the patient. If thirst exists, the milk is diluted with water, but more than two liters of total liquid is seldom given. This cure is very simple and can be carried out anywhere; the rapidity of the loss of weight may be regulated by the quantity of milk given. Patients with cardiac or renal affections are very favorably affected by the treatment. An untoward symptom is constipation, which frequently accompanies exclusive milk diet, but this is easily overcome by proper medication or enemata. The feeling of hunger is never as intense with the use of this diet as with many other forms of treatment by means of dieting. Headache is often complained of, but it does not last very long after the cure has been followed for a few days. The great advantage, in addition to the cheapness and simplicity of the method, is its easy adaptation to each individual patient by the increase or diminution of the quantity of milk allowed.

Nontuberculous Consolidation of the Apex of the Right Lung.—Blümel says that Krönig has for many years observed a symptom complex suggesting tuberculosis, and accompanied by signs of induration in the right pulmonary apex. Such patients are usually mouth breathers from early childhood, and the mere lack of ventilation of the apices leads to the physical signs which are often mistaken for tuberculosis. The use of tuberculin and the further course of the disease usually prove the innocent nature of the affection, depending, as it does, upon mechanical conditions and not upon a specific infection. The inhalation of dust, the passage of which to the lungs is not prevented in the case of mouth breathers, leads to interstitial bronchitis and pneumonia, which are responsible for the physical signs of the affection. The therapy consists of treating the intranasal conditions responsible for the mouth breathing.

Deutsche medizinische Wochenschrift, July 9 *and* 23, 1908.

The Effect of Measles on the Cutireaction with Tuberculin.—V. Pirquet has noticed no diminution in the reaction to cutaneous inoculation with tuberculin in tuberculous children affected with measles up to two days after the onset of the disease. The reaction then progressively diminishes and is usually absent by the fourth day after the exanthem. It becomes again perceptible after this day and gradually assumes its former character before the attack of measles is over. V. Pirquet examined altogether 159 cases of measles in reference to the behavior of the reaction described by him and the great majority of them gave results stated above. Analogous phenomena may be observed in mili-

ary tuberculosis, in cachectic individuals, and in connection with the injections of large amounts of tuberculin. The reaction, however, does not reappear in these instances as it usually does in the case of measles. In the latter instance it may be due to the rapid spread of the infectious process which often accompanies the appearance of measles in tuberculous children. No such phenomenon could be observed in scarlet fever, in diphtheria, in epidemic cerebrospinal meningitis, or in typhoid fever. Vaccination, however, has a similar effect upon the cutaneous reaction. The result of the inoculation may be used in differential diagnosis between measles and other diseases attacking a tuberculous child. The persistence of the cutaneous reaction in a tuberculous child suffering from a suspicious exanthem speaks strongly against measles. V. Pirquet has thus differentiated two cases of rubeola and one of erythema multiforme from measles.

The Frequency of Mitral Stenosis.—Hampeln says that pure mitral stenosis is a frequent affection, both in an anatomical and clinical sense, composing about 10 to 20 per cent. of all lesions of the mitral valve. The most important sign of such involvement of the valve is found in the accentuation of the first mitral sound and the presence of a presystolic murmur at the apex. The latter may only be slightly developed or even quite imperceptible. The second pulmonic sound is usually markedly accentuated; but this accentuation is not heard best at the normal pulmonic area, in the second left interspace, but further down, at the junction of the third or fourth rib with the sternum, or even at the lower portion of the sternum and its borders. Pure mitral stenosis is the most benign of all valvular affections, and is therefore often unrecognized, the insignificance of the murmur combined with the lack of symptoms serving to hide its existence.

Method of Culturing Meningococci.—Conradi says that the presence of Gram negative intracellular diplococci in the spinal fluid of patients suffering from meningeal symptoms gives the diagnosis of cerebrospinal meningitis. Often enough the mere microscopical examination is not conclusive, if the bacteria are not found in the cells or are very few in number. In such cases culturing the fluid is necessary, agar with ascitic or hydrocele fluid being used. The latter fluids are not always to be obtained, and, instead of them Conradi uses the very spinal fluid obtained from the patient as the culture medium. This fluid is obtained under aseptic precautions, is then centrifuged, and the clear supernatant liquid heated for one or two hours at 60°. Then it is divided into three portions and each added to some neutral agar, which is then poured into Petri dishes. The sediment remaining from the centrifuging is spread over the surface of this medium, and each inoculated dish is placed into a larger dish, which contains some cotton wet with 1 per cent. solution of bichloride of mercury. In this damp chamber the meningococci grow as well as upon the usual culture media.

Operative Treatment of Tuberculosis of the Foot.—Stich says that radical treatment has been found to be the best in dealing with the tuberculosis of the joints of the feet. Operation is undertaken in all cases in which the focus of disease may be removed before the joint is involved; if the joint is involved, conservative treatment may be tried only in the case of young individuals showing marked resistance to the spread of the infection, the *x*-ray picture testifying to the fact that only a small portion of the bone is affected. In all other cases operation is indicated without any previous attempts at conservative treatment, in the absence of other contraindications to operative procedures. In 73 per cent. of cases conservative treatment was begun, but the results were so unsatisfactory that, later, operative treatment was used in 77 per cent. of these. The best mode of procedure consists in the larger resections, the removal of too little tissue being frequently followed by recurrences.

French and Italian Journals.

The Incomplete Cure of Insanity.—F. Petro discusses the proper treatment for certain cases of insanity in persons predisposed to nervous disorders who live for a long time normally in society until some lack of success, the death of a relation, or some unusual strain destroys the mental balance, and they must be placed under control to avoid injury to others. These persons, after the cessation of the acute symptoms, become practically sane and remain so as long as they continue in the routine of the institution, living a healthy, regular life. If they are sent away from the asylum they relapse into the original condition and must be returned to the institution. While they remain there they are able to work, to aid in the routine of the institution, and to continue useful members of society, although they are not able to struggle against the ordinary odds of outside life. They remain at the institution willingly, even gladly, being conscious that this protected life is better for them. The author believes that for such cases there should be established a sort of colony life, not in but connected with the asylum, where they may remain and live a regular life, with useful employment. Such colonies should belong to several communities, since the number of such cases is comparatively small. This system of care would lessen the number of casualties that happen by relapses in such cases after they have been liberated.—*Rivista Italiana di Neuropatologia, Psichiatria, e Elettroterapia,* May, 1908.

Maceration of the Fetus in Relation to Legal Medicine.—G. Pisane, after a study of sixteen fetuses that had undergone maceration, with reference to the reliable signs of maceration and the length of time since death occurred, gives us his results tabulated. He states that the fetus is very flaccid, all the serous cavities are filled with imbibed fluid, the bones of the cranium are loose and flap about, and all the tissues and organs have imbibed blood pigments. The endothelium of the blood-vessels becomes softened and detached, and the blood pigment then passes out into the tissues. He finds that the amount of coloration varies with the length of time since death, increasing gradually. This pigmentation is of scientific importance and may be used for diagnosis if properly limited, but used too widely it may lead to mistakes.—*Annali di Ostetricia e Ginecologia,* March, 1908.

Mode and Duration of Contagion in Scarlatina.—Zilgien thinks that we are passing from the phase in which we believed that scarlatina was most contagious during the stage of desquamation into one in which we recognize the fact of its marked contagiousness during the period of the angina. He believes from his observation of such cases that after the acute symptoms in the throat have ceased in many cases the patient may be allowed to mingle with society without danger. The products of expectoration from the throat are the most dangerous means of carrying the disease. In other rare cases the contagion appears to continue long after desquamation is complete. The author describes a case in which there was severe angina and isolation was carried out. Some time later another attack of angina occurred and in this also isolation was carried out, and no contagion was carried to any other person, although a profuse desquamation went on for several weeks. To offset this case he describes an epidemic occurring in a school, in which one child seemed to be the source of contagion to others long after desquamation was complete. The author believes that the means of contagious infection is generally a suppuration of the middle ear, or the presence of adenoids, or hypertrophied tonsils, in which the means of infection is carried for a long time. Prophylactic treatment would include the care of the throat and nose especially, and their daily disinfection as long as suppuration lasts.—*Journal de Medicine de Paris,* May 16, 1908.

Treatment of Cancer of the Female Genital Organs.—J. O. Faure describes his experience in the treatment of cancer of the female genital organs and his results. There can be no divergence of opinion as to the operative treatment of cancers of the external genital organs, tubes, and ovaries. The only appropriate treatment is removal wide of the growth and as early as possible. Cancer of the vulva requires the removal also of the inguinal glands of both sides. For cancer of the fundus the preferred operation is abdominal hysterectomy. It is sometimes advisable to leave the cervix, since this is generally entirely normal, and recurrence occurs not there, but in the pelvic glands. Total hysterectomy is to be preferred, however. Cancer of the vagina is to be treated as cancer of the vulva is—when occupying the lower two-thirds, being removed as that of the vulva is. When higher up it is almost impossible to remove it without taking away the uterus also. The vaginal route is not to be thought of, since it is impossible to see the boundaries of the growth on account of the narrow space and the hemorrhage that occurs. Cancer of the cervix should also be removed by abdominal hysterectomy for the same reasons. The author ligates the hypogastrics and removes all the glands that can be easily felt with the finger. To remove all the glands and cellular tissue is impossible, and the attempt is not advisable, since it opens to infection the large cellular spaces. The author's series of cases operated on between 1903 and 1905 includes eighteen cases, of which ten are alive and apparently cured. These durable results the author considers good. His later cases are too recent to be sure that recurrence will not occur.—*Annales de Gynecologie at d'Obstetrique,* June, 1908.

Book Reviews.

American Practice of Surgery. A Complete System of the Science and Art of Surgery by Representative Surgeons of the United States and Canada. Editors: Joseph D. Bryant, M.D., LL.D., Albert H. Buck, M.D., of New York City. Complete in Eight Volumes. Profusely Illustrated. Volume IV. New York: William Wood & Company, 1908.

This volume treats of Dislocations, Operative Surgery, and Orthopedic Surgery, the various chapters being contributed by sixteen authors. The first of these subjects is from the pen of Dr. Emmet Rixford of San Francisco, and the article, of only a little over one hundred pages, is perhaps one of the most concise, yet complete, and altogether satisfactory treatises on the subject that it has been our good fortune and pleasure to read. The illustrations, both *x*-ray plates and wood cuts, are numerous and excellent. The division of Operative Surgery begins with an excellent and practical essay on the influences and conditions which should be taken into account before one decides to operate. Dr. Nancrède of Ann Arbor, the author, discusses here many points which seldom receive adequate, if any, attention from writers on surgery, and many of the cautions he utters against operating at an inopportune time or in unsuitable cases should receive very respectful attention from the young surgeon, and even some of the older generation might read the article with profit. The preparation for an operation, the operation itself, and the care of the patient during and immediately after the operation are treated of by Dr. George Ben Johnston of Richmond, Va. The writer favors the use of gloves by the operator, though recognizing the increased danger of sepsis in case the glove is torn or punctured. For hand disinfection he relies entirely on "soap and water plus time and elbow grease," and has discarded bichloride, permanganate, and all other antiseptic solutions. In the chapter on Anesthetics Drs. Freeman Allan and F. E. Garland of Boston give an excellent description, with practical details, of the various methods of inducing general anesthesia, together with indications for the choice of anesthetic in individual cases. This is followed by a chapter on Local Anesthesia, including spinal anesthesia, by Dr. James F. Mitchell of Washington. Drs. William L. Rodman and John Stewart Rodman of Philadelphia contribute a thoroughly practical chapter on Amputations and Disarticulations, and Dr. Horace J. Whitacre of Cincinnati one on Excision of Bones and Joints. The section on Ligature of Arteries and Veins in Their Continuity is by Dr. John M. Keyes of New York; that on Minor Surgery (including Bandaging) by Dr. Russell S. Fowler of Brooklyn, and on Plastic Surgery by Dr. James S. Stone of Boston. This volume also contains some chapters on Orthopedic Surgery, namely, Congenital Dislocations and Infantile Paralysis by Dr. Charles F. Painter of Boston, Torticollis by Dr. George D. Stewart of New York, Deformities and Disabilities of the Lower Extremities by Dr. Royal Whitman of New York, and Tuberculous Diseases of the Spinal Column and the Deformities Resulting Therefrom by Dr. Clarence L. Starr of Toronto. As the successive volumes of this well written and carefully edited work appear, the conviction is forced on the reviewer that there is nothing in the English or any other language that will compare for completeness and finality with this treatise.

Why Worry? By George Lincoln Walton, M.D., Consulting Neurologist to the Massachusetts General Hospital. Philadelphia and London: J. B. Lippincott Company, 1908.

This is a most readable little book, full of optimism, and one that cannot fail, for the time at least, to impress upon the chronic worrier the folly of his worry. It is doubtful whether it will work a lasting cure in the inveterate pessimist, for his disease is beyond the reach of argument or even banter, but the young man or woman who is beginning to fuss and fume over the little bothers of life or even to be overanxious concerning the really serious things may be led to see the futility and the harm of such a mental state by a perusal of Dr. Walton's cheery book. The author's style is chatty and cheerful, but the book is full of wisdom as well, and there are many little nuggets of sound sense, lightly expressed, which the reader finds himself thinking over after he has closed the book and which are likely to occur to him at times when a cheerful thought is most needed. The author's argument may be summed up in the Irishman's advice to "be aisy, and if you can't be aisy, be as aisy as you can," and he shows that one often can be much happier than he thinks he can if he will only try. His advice to the over-particular, the people with a "New England conscience," in the chapter on "Maxims Misapplied," is excellent, not as an excuse for the shiftless, but is a corrective to the overworking neurasthenic who insists on never putting off till to-morrow what can be done to-day, not seeing that he may be able to do it much better to-morrow, when his mind and body are fresh, than he can when fagged out to-day.

A Manual of the Diseases of Infants and Children. By John Ruhräh, M.D., Clinical Professor of Diseases of Children in the College of Physicians and Surgeons, Baltimore. Second Edition, thoroughly revised. Philadelphia and London: W. B. Saunders Company. 1908.

The new edition of this little book follows out the methods of its predecessor in being primarily a compact synopsis on the subject of pediatrics, of use to students whose time for any special subject is limited by the great extent of topics necessarily covered in the college curriculum. The chief novelties consist in the addition of sections on inspection of school children and on the rules to be observed after contagious illnesses so that the spread of diseases may be lessened.

The bibliography is brought up to and through 1906 and has been largely limited, as the author states, to recent articles written in the English language. Good judgment in limiting these references has been shown, the author evidently realizing as a teacher that ideally complete knowledge of all that is written is impossible if not inadvisable.

Typhoid Fever: Its Causation, Transmission, and Prevention. By George C. Whipple, Consulting Engineer. New York: John Wiley & Sons, 1908.

This timely work deals exclusively with the problems of transmission and prevention of typhoid, and as it is written by an engineer it wisely limits the bacteriological parts to a minimum and wholly omits the question of treatment. Though it professes to be a mere summary for the use of physicians and engineers, it is in reality a bigger book than the author imagines, for he has written something which should be in the hands of every intelligent layman, no matter what his calling, but it is particularly valuable to all public officials. In the introduction, Prof. W. T. Sedgwick states that as the disease was formerly a scourge and progressively lessens as civilization advances, its frequent occurrence means defective civilization, and the author is particularly severe upon the shameful prevalence in the Southern states.

It is curious to note that the medical profession has been proverbially slow in recognizing the contagiousness of typhoid—a fact pointed out in 1873 by Dr. Wm. Budd in England in opposition to the medical profession—a theory instantly accepted by Prof. Tyndall with that wonderful insight which placed him a generation ahead of his times in so many other matters. Only recently have military physicians accepted this theory and acted upon it, but the results are already grand, for soldiers have less than half the sick rate of civilians of equal age.

Besides describing numerous epidemics, the methods of controlling them, and the influence of water and milk in spreading the bacilli, the author gives excellent rules for prevention and in the appendix he has quoted numerous articles on subsidiary topics, all of which can be commended except the praise of the Japanese, who really had a deplorable sick rate. The book is charmingly written in simple language and deserves to become a classic in the urgently needed campaign of education to end typhoid—for every death is preventable and perhaps the profession has been sorely derelict of its duty.

Hematological Atlas, with a Description of the Technic of Blood Examination. By Priv. Doz. Dr. Karl Schleip, Scientific Assistant Medical Clinic University of Freiburg i/B. English Adaptation of Text by Frederic E. Sondern, M.D., Professor of Clinical Pathology New York Postgraduate Medical School and Hospital, Director of Clinical Laboratory New York Lying-In Hospital. With 71 Colored Plates. New York: Rebman Company, 1908.

Those who are familiar with the German original of this work will feel that American readers are to be congratulated in having an English adaptation of it made available for their use. The translator has deviated but little from the author's text and has faithfully preserved its general tenor. The colored illustrations are of course identical with those of the original and represent the highest order of excellence. It must be admitted, however, that the use of a white paper as a background for the plates is an unfortunate change, for the gray paper employed for this purpose in the German edition makes a highly effective contrast, such plates as I, IV, and V, for example, losing much in appearance on the white surface. There seems also no very good reason for increasing the size of the margins so very much as has been done: the volume is thereby made more bulky without any gain in appearance. The atlas is a very beautiful example of modern skill in lithography and should appeal strongly to all interested in hematology.

A Mind That Found Itself. An Autobiography. By Clifford Whittingham Beers. New York, London, Bombay and Calcutta: Longmans, Green and Co., 1908.

We predict that this book will be widely read and that it will accomplish much good in the direction of more general humane treatment of the insane. It is written, says the author, "by one whose rare experiences impel him to plead for those afflicted thousands least able to speak for themselves." These experiences happened for the most part in three institutions for the care and treatment of the insane, in which the author was confined for nearly three years. The form of his mental disorder was apparently manic-depressive insanity, a form which is curable, and also one in which it is not uncommon that memory pictures of personal experiences and observations, during much of the period of alienation, may later be recalled with a vividness scarcely realizable to those who have had the patient in charge. In this instance, the narrator gives us, in minute detail, a most graphic account of the evolution of his psychosis and the genesis of his delusion, while he describes, in a fascinating way, his thoughts and experiences while insane, and the nature of the treatment he received. From the description, his "treatment" was, for the most part, tactless, heartless, and unsuited to the case, and, during the maniacal stage, often brutal in the extreme. In spite of this latter fact, however, the book is written in a temperate, judicial and forgiving spirit and it will challenge general as well as medical interest. It is but just to say that the abuses disclosed by Mr. Beers have been rapidly disappearing from many American institutions for the insane since the more uniform adoption of non-restraint; the advent of more liberal financial policies; competitive examinations for medical positions; and the existence of training schools for attendants.

The Theory and Practice of Hygiene. (Notter and Firth.) Revised and largely rewritten by R. H. Firth, Lieut.-Colonel Royal Army Medical Corps, formerly Professor of Hygiene in the Royal Army Medical College, etc. Third Edition. Philadelphia: P. Blakiston's Son and Company, 1908.

There is very little concerning the theory and practice of hygiene that is not to be found between the covers of this voluminous treatise. Originally the work of Dr. Edmund A. Parkes, it was rewritten in 1896 by Colonel Notter and Lieut.-Colonel Firth, and now appears in greatly amplified and practically new form as the product of the industry of the latter author. It is marked throughout by a completeness and attention to minutiæ often overlooked that should render it invaluable both as a work of reference and as a guide in practical work. While the large amount of matter concerning legislation bearing on the subject is of course primarily of interest to British readers, the bulk of the volume is exceedingly practical in nature and is well adapted for the use of medical men of any nationality. Particular attention has been given to the subject of water supplies, and stress is laid on the microscopical examination of water sediments, a subject that has been somewhat neglected of late owing to the greater importance of the chemical and bacteriological aspects of the question, but which none the less is not devoid of either interest or significance. A series of excellent plates illustrates the commoner animal and vegetable forms encountered. Another chapter of the greatest value is that on vital statistics; a difficult subject, whose scientific foundation is largely the work of Professor Karl Pearson. It is an unfortunate but unassailable truth that, as the author says, a working knowledge of the higher mathematics is as essential for the health official as is acquaintance with bacteriological technique. The last two chapters of the book are devoted to the subject of the sanitation of naval and land forces, and present what is practically a summary of the field of preventive medicine. The work is very fully and satisfactorily illustrated, and is undoubtedly one of the most complete and practical books on hygiene ever published.

Diets in Tuberculosis. Principles and Economics. By Noel Dean Bardswell, M.D., M.R.C.P., F.R.S. (Edin.), Medical Superintendent, King Edward VII Sanatorium, and John Ellis Chapman, M.R.C.S., L.R.C.P., Medical Superintendent, Coppin's Green Sanatorium. London: Henry Frowde, Oxford University Press; Hodder & Stoughton, 1908.

There is no more promising field for clinical research in therapeutics than that which appertains to dietetics in general and to the principles and economics of diets in tuberculosis in particular. The stuffing process so long in vogue, under which the chief aim has been to force the maximum intake of heavy nitrogenous food compatible with the patient's tolerance, regardless of its physiological suitability, has at last provoked a protest on the part of those who have had the widest opportunities for scientific observation and study of the relative effects of over-feeding on the one hand and physiological dieting on the other. Among the earliest and most zealous to give this subject of diets in tuberculosis the attention which it so much deserves were the authors of the present work, and their experience and practical study of the subject gives added authority to their work.

The present volume incorporates the results of their investigations, extending over some seven years, and which have been made possible in large measure by a grant from the Government Grant for Scientific Investigation Made by the Royal Society. The authors have shown very clearly that the average among the consumptive poor, where every penny counts, spend much more for an adequate diet than is in any way necessary, and that this is because of ignorance as to food values and food preparation. If every physician who has to do with the consumptive poor were to familiarize himself with the facts which are so forcibly set forth in this little work, the greatest economic benefit would result both to individuals among this class of invalids and to institutions devoted to the treatment of tuberculosis where, it is well known, the dietary is usually extravagant out of all proportion to its nutritive value. It is interesting to note in the Appendix of this little book that an adequate dietary in the treatment of pulmonary tuberculosis can be so constructed as to cost in England about 16 cents per day. It is, of course, possible that so small a figure could not be approached in this country, but, on the other hand, it is certain that with intelligence in buying and skill in preparation, an adequate dietary could be provided in many parts of this country within 20 or 25 cents, whereas at present 30 to 50 cents per day represents the cost of such dietaries as are usually prescribed for the consumptive, irrespective of his financial condition. This little book is to be recommended to the careful perusal of all physicians and sanatorium superintendents who have to do with the treatment of tuberculosis.

A Manual of Fever Nursing. By Reynold Webb Wilcox, M.A., M.D., LL.D., Professor of Medicine at the New York Post-Graduate Medical School and Hospital; Consulting Physician to the Nassau Hospital; Visiting Physician to St. Mark's Hospital, etc. Second Edition. Revised. Illustrated. Philadelphia: P. Blakiston's Son & Co., 1908.

This volume contains the lectures on fever nursing which were delivered to the nurses of St. Mark's Hospital. It commences with four introductory chapters, which contain much general information on such subjects as diagnosis, thermometry, hydrotherapy, diet, general treatment, disinfection, quarantine, etc. The various fevers are then discussed in turn and detailed information is given on every subject that can possibly be of any interest or concern to the nurse. For nurses this book is ideal, and will prove of more real value than several of the more pretentious volumes which profess to deal with the practice of medicine.

Traité Pratique de Thérapeutique Infantile Medico-Chirugicale. Par les Docteurs Le Gendre et Aug. Broca. Deuxieme édition complètement refondue. Ouvrage récompensé par l'Académie des Sciences et l'Académie de Médecine. Avec un formulaire, un tableau posologique et 170 figures dans le texte. Paris: G. Steinheil, 1908.

The first and smaller part of this book is given up to the consideration of the special elements in the therapy of childhood and to a general review of the means of treatment at the disposal of the pediatrists. Among them the most attention is properly given to nutrition: the choice of the wetnurse, the hygiene of a nursing woman, artificial feeding with modified milk mixtures are here fully considered. Then follow short but sufficient remarks on the external means of treatment, such as baths, mineral waters, electricity, etc.; general considerations about the administration of drugs and their dosage close this part of the book. The second part is given up to the special treatment of the various medical and surgical affections, arranged in alphabetical order. This, of course, does not allow any systematic presentation of the therapy of diseases classified either according to their etiology or to the organs involved. The book wins much, however, in the readiness with which it may be consulted. The work being arranged specially for such use, it may be questioned whether the giving of the operative technique in cases of surgical diseases, such as appendicitis, was well advised; the descriptions are not extended enough to be of real use to the practical surgeon, and the alphabetical arrangement of the book certainly stamps it as not intended for students. In other respects, the therapeutic advice given is full and well selected, cross-indexing is frequent, and the work, as a whole, forms a very useful book of reference in therapeutics of children.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

66th Annual Meeting, Held in Sheffield, July 24-31, 1908.

(Special Report to the MEDICAL RECORD.)

SECTION OF SURGERY.

Wednesday, July 29—First Day.

Diagnosis and Treatment of Malignant Disease of the Breast.—Sir W. WATSON CHEYNE, Bart, C.B., F.R.C.S., introduced the subject. Dealing first with the diagnosis of mammary cancer, he pointed out that manipulation of the diseased breast was capable of causing displacement and migration of cancer cells, the risk being greater in the case of deep-seated and doubtful growths. Hence undue handling or squeezing during examination should be avoided. Comparison of the two breasts was valuable to ascertain the position of the nipples, the presence of dimpling of the skin, and adhesion to underlying fascia. The nipple occupied a higher level in the diseased side—a feature also seen in mastitis. The relative mobility of the breasts in the direction of muscular fibers should be observed. The margin of a cancerous lump was often ill-defined owing to the drawing in of surrounding gland tissue. A deeply placed cyst might simulate growth; an exploring needle was then useful, and if fluid was found it should be withdrawn and a little carbolic acid injected to effect a cure. When a diagnosis had to be made by means of an exploratory operation, the presence of a pathologist was required at the time. The growth must on no account be cut into *in situ*, but approached through a wide incision, and if found to be cancerous, the operation should forthwith be completed. Turning to the question of operative treatment, he claimed that the propriety of extensive removal had been established by its results. The three guiding principles of operation were (1) complete extirpation, (2) the avoidance of disseminating cancer cells, and (3) the achievement of good functional results. With regard to (1) economy of skin was not permissible in the case of superficial growths, though more skin could be left when the growth was deep. Angular incisions were often useful. Fascia should be removed more extensively than skin, and to insure this being done, the underlying muscular fibers should also be taken away. Downwards and backwards fascia must be dissected from the upper part of the rectus abdominalis and from a wide area over the latissimus dorsi and serratus magnus. He removed the whole of the pectoralis major, excepting its clavicular portion, and the pectoralis minor as well. The costo-coracoid membrane was also removed. All the axillary fat and cellular tissue were taken away in one piece, much stress being laid on the importance of working from the apex of the axilla downwards. In some cases the posterior triangle of the neck needed to be cleared, and the opinion was expressed that this procedure was not often enough done. (2) To guard against infection by displaced cancer cells the growth must nowhere be cut into or squeezed; and the axilla should be dissected by beginning at the apex of that space. As to (3), viz., good functional results, the sequel was usually satisfactory, and it was unnecessary to make special connections with the deltoid or other muscles. The tendon of the pectoralis major should be cut close to the bone, so as not to leave a thick stump. During the time of healing his practice was to keep the arm at right angles to the trunk, the limb being afterwards massaged.

Dr. HAROLD STILES, referring to diagnosis, classified doubtful cases in two groups: (1) benign tumors liable to be mistaken for cancer, and (2) malignant tumors resembling innocent ones. While not favorable to exploration by cutting into a growth, because of the danger of grafting cancer-cells, yet, if this were done, the application of a five per cent. solution of nitric acid by coagulating cancer-cells would serve to distinguish between carcinoma and mastitis. In the case of the colloid form of growth he raised the question whether a radical operation was invariably necessary. He preferred chloroform as the anesthetic, believing there was less bleeding than when ether was employed. As regards operative technique, he recommended long skin incisions—eighteen inches not being an excessive length, and he removed the pectoralis minor completely in order to facilitate access to the apex of the axilla and the clearing of that space from above downwards, which was an essential step. The posterior thoracic nerve must be carefully preserved when working towards the root of the neck behind the axillary vessels. Glandular infection above the clavicle sometimes meant an extension of disease from the mediastinum, and in such cases a radical cure was impracticable.

Mr. RUTHERFORD MORISON thought that the discrimination of carcinoma of the breast from tuberculosis, cystic disease, and abscess was not always possible by external examination. He advised removal of glands from the posterior triangle. In young women the ovaries should be removed, because pregnancy after excision of a cancerous breast greatly increased the liability to recurrence. In the after treatment he considered exposure to *x*-rays was beneficial, and he insisted on the value of an out-of-door life.

Mr. LYNN THOMAS remarked on the clinical difference exhibited by cases which appeared to be identical in their histological characters, the tendency to recurrence showing a wide range of variation. He was in favor of using the *x*-rays; and, in regard to choice of anesthetic, preferred ether administered by the open method.

Mr. EDRED CORNER entered a plea for improvement in the means of making an early diagnosis. Only a minority of the cases submitted to operation could be spoken of as cured, the reason being that excision was done too late.

Mr. CRISP ENGLISH considered the most important of the early signs of cancer was impaired mobility of skin over the growth. He cited two cases of mammary tumor occurring in young women, aged respectively 20 and 24, in whom small tumors were mistakenly thought to be adenomata, whereas they were, in fact, malignant. Both these cases showed puckering of the skin when the lump was pulled upon. He preferred chloroform as the anesthetic.

Mr. CHARLES RYALL did not remove the pectoralis minor as a rule, and argued that each case should be treated on its merits. Division of the clavicle facilitated removal of the chain of glands extending up the posterior triangle. He objected to excision of the tumor for examination.

Mr. SAMPSON HANDLEY said that since metastasis through the lymphatics in the upper abdominal wall were not infrequent, the pelvic viscera ought to be examined for recording growths. Too much skin should not be sacrificed, but the flaps should be undermined so as to insure a wide removal of the fascia in whose planes the cancer tended to spread. Halstead's operation was unsound because it did not sufficiently meet the requirement of undermining the skin. Cancer diffused itself locally not by embolism, but by *permeation* in all directions equally; and, therefore, the growth must be the center of the parts. Failure to recognize this fact explained the unsatisfactory result which often followed removal of tumors in the periphery of the breast. Recurrence at the end of an intercostal space was due to extension from the chest where malignant cells were already present at the date of operation. After amputation of a cancerous breast it was his practice to submit the patient to eight applications of *x*-rays as a prophylactic. He strongly supported Mr. Morison's view as to the value of an open-air life.

Mr. WILMOTT EVANS was opposed to incising a doubtful growth *in situ*: it should be removed widely, and, if found to be malignant, fresh instruments and swabs should be

used in completing the operation. The incision should continue over the shoulder to a point one inch in front of the acromion; this gave free access to the apex of the axilla. As the axilla was a quadrilateral space, it was a mistake to keep the arm at right angles or to bind it to the trunk, because in either case two opposite walls were made to adhere, and the range of movement was thereby lessened. He preferred to bandage the trunk, and the arm separately right up to the top of the axilla.

Mr. Keith Monsarrat held that there was no standard operation, the amount of tissue to be removed in any given case being governed by the extent of disease. In a doubtful growth he advised taking out a small piece under local anesthesia; and, if necessary, the radical operation could be done two days later.

Mr. Douglas Drew was convinced that colloid cancer demanded a no less complete operation than scirrhus, and he cited two cases in support of this opinion. Both the pectoralis major and minor should be removed as a routine step in amputation of the breast for cancer; in his series of seventy cases so treated there was not a single death. He invariably drained the wound by an opening in front of the scapula.

Dr. Robert Bell protested against any operative treatment for cancer, whether in the breast or in any other organ.

Mr. Crawford Renton was in favor of exploratory incision when the signs of cancer were ambiguous. For malignant growths radical operation was imperative. Supraclavicular glands must be removed if not infected so seriously as to suggest disease beyond their limits.

Dr. J. B. Murphy of Chicago agreed generally with the views expressed by Sir Watson Cheyne. He made an energetic defence of ether as the best anesthetic during the performance of the operation under discussion.

Prof. Jordan Lloyd, after ample experience, had come to the conclusion that many cases of breast cancer were not benefited by operation. He had seen patients with the disease in a chronic form surviving for many years without any surgical interference.

Thursday, July 30—Second Day.

Indications for the Performance of Nephrotomy and Nephrectomy.—Dr. David Newman of Glasgow opened this discussion, the object of which he said was to fix the present position in regard to operations on the kidney. The symptoms which called for attention were: (1) pain, spontaneous and reflex; (2) sensitiveness on pressure; (3) frequent micturition; (4) vicarious action of other organs; (5) anuria. Symptoms in renal disease were very equivocal and needed physical corroboration, as exact and early diagnosis were most desirable. The objective methods of most value were: (1) Cystoscopy; (2) segregation of the urine from each ureter; (3) estimation of urea in each sample; (4) methylene blue test; (5) bacteriological examination of the urine, including inoculation experiments, and ophthalmotuberculin reaction; (6) sounding the ureters; (7) cryoscopic index of blood and urine; (8) radioscopy; (9) exploratory incision. Special attention was called only to the value of cystoscopy, radioscopy, and the objects and conditions which justified direct exploration, namely, (1) to determine the condition of the opposite kidney before a nephrectomy; (2) in traumatic lesions of the kidney giving rise to grave symptoms; (3) in cases of sudden anuria where medical treatment had failed to give relief; (4) in cases of doubtful diagnosis, especially in those suspected to be malignant tumor, tuberculous disease, and in calculous disease with sepsis; (5) for the relief of tension due to mechanical congestion, inflammatory hyperemia, or subcapsular extravasation of fluid. Nephrotomy was performed to expose and treat perinephritic lesions, to relieve vascular tension of the parenchyma or fluid distention of the pelvis or to enable the surgeon to remove a foreign body or a benign tumor from the kidney or its pelvis. Having opened the kidney, the following questions required to be considered: "(1) What is the general condition of the patient? (2) Is the lesion one that can be remedied or removed by nephrotomy? (3) If so, should it be dealt with at the time or by a subsequent operation? (4) Is the kidney so destroyed that it is functionally useless, and only a source of trouble and danger to the patient; and if so, is it safer to excise the kidney now or at a later date? (5) Is the lesion one which from its nature if allowed to remain is inconsistent with life, and should the disease be removed at once?" Primary nephrectomy was permissible only when the disease seriously threatened life, either on account of the nature of the malady or because other less serious operations had failed; it was necessary in primary tuberculosis, in malignant disease, and in serious injuries to the kidneys.

Mr. John Pardoe discussed the question of differential diagnosis from the standpoint of localization of the particular urinary viscus affected. Mimicry of kidney disease by lesions of the bladder and *vice versâ*, was not infrequent. He cited the case of a woman with a large left lumbar tumor associated with bright red blood in every micturition; cystoscopy revealed a papilloma of the left ureteral orifice, and on removal of the growth the renal tumor subsided and the hematuria ceased. Vesical calculus might also be simulated by a stone in the ureter, as illustrated by the case of a man with hematuria, penile pain, and sudden stoppage of the stream of urine; the cystoscope showed a stone in the mouth of the ureter; free diuresis caused the stone to pass and cure followed. In "symptomless" hematuria, *i.e.* where the only symptom is blood in the urine, cystoscopy is the chief means of diagnosis. To distinguish which of the two kidneys is diseased, attention must be paid to the appearance of the ureteral orifices, and to the character of the efflux therefrom, both as regards rapidity and regularity. Ureteral catheters and the segregator were also of value, but he objected to indiscriminate catheterization of the ureters, because this procedure was not free from danger, especially in septic cases. While in favor of conservatism in renal surgery, he did not agree with Dr. Newman in treating a septic kidney by prolonged drainage, nephrectomy being preferable.

Mr. Thelwall Thomas laid stress on the value of skiagraphy, and of bacteriological examination of the urine. In his experience of renal calculi, calcium salts were generally present and not uric acid. He regarded a septic kidney as too dangerous a condition to justify long-continued drainage through a sinus, unless the patient were under close and constant observation. He found that tuberculin gave satisfactory results in renal tuberculosis.

Mr. Andrew Fullerton remarked on the simulation of kidney disease by membranous colitis and appendicitis. He thought catheterization of the ureters superior to the use of a segregator for obtaining the secretion of each kidney separately. He found the specific gravity of the urine from a kidney containing stone or tubercle distinctly lower than that of the urine from its healthy fellow. He would remove a tuberculous kidney as soon as the diagnosis was certain, provided that the other kidney was sound. With regard to the injection of fluid into the bladder, overdistention was liable to the risk of forcing morbid material into a healthy bladder.

Mr. Leedham-Green pointed out that tuberculosis of the urinary organs began as a rule in the kidney and extended downwards to the bladder; and whereas small nodules in the cortex might heal, deep tuberculous foci usually progressed to a fatal ending. From several years' experience of tuberculin he found general improvement in respect of gain in weight and abatement of symptoms, but in not a single case of renal tuberculosis had he effected a cure by tuberculin. He was in favor of early nephrectomy before the vitality was sapped and the bladder infected. He

found tubercle bacilli present in a large percentage of cases of albuminuria. To obtain the secretion of each kidney, catheterization of the ureters with the aid of a cystoscope was superior to all other means. The functional activity of the kidneys should be estimated by examining the urine from each chemically, physically, and bacteriologically, the observations being spread over several days. For testing renal activity phloridzin was a better agent than indigo carmine. Cryoscopy of the blood was useful in children. He would not remove a tuberculous kidney if the opposite organ was badly diseased.

Mr. Lynn Thomas advocated conservative surgery in renal disease. He quoted cures following prolonged drainage in cases respectively of calculous pyelitis, hydatid of the right kidney, and tuberculous pyonephrosis.

Mr. Deansley urged that cystoscopy should be a routine practice in the investigation of surgical disease of the kidneys, and before operating on one kidney the functional condition of the other should be ascertained. In performing nephrotomy, the cortex should not be opened if the pelvis of the kidney could be entered; it was not sufficiently known that a pelvic wound heals readily without fistula. Nephrectomy was required in cases of renal tubercle beyond the early stage; and the same operation was indicated, rather than drainage, for chronic pyonephrosis.

Mr. R. Kennedy advocated the routine use of the cystoscope and segregator. In cases of neoplasm of the bladder or prostate attended by cystitis and pyelitis, he advised preliminary nephrectomy and drainage of the diseased kidney fourteen days before dealing with the primary disease by cystotomy.

Dr. J. B. Murphy called attention to a class of cases in which valvular or cicatricial obstruction of the ureter near its origin caused periodic retention in the kidney pelvis. He had successfully treated eleven such cases by resection of the diseased site and reattachment of the ureter to the pelvis. He pointed out that removal of one kidney was liable to cause congestion and edema of the other kidney, and therefore temporary renal drainage was a valuable procedure prior to nephrectomy in suitable cases.

Mr. Clay gave details of a case of multiple renal calculi whose removal caused profuse hemorrhage, requiring the retention of clips for some hours. He left the kidney outside the loin, replacing it after several days, and a cure followed.

Mr. Paterson, referring to "symptomless" hematuria, cited a case of angioma of the kidney pelvis which he cured by the use of a sharp spoon and zinc chloride. He agreed that incisions into the pelvis and ureter tended to heal readily; and he held that preliminary drainage of a kidney would, in certain cases, diminish the risk of a fatal issue when the necessary nephrectomy was subsequently performed.

Dr. Newman replied. He was less fond of segregation than formerly; nor did he practise catheterization of the ureters so frequently because it involved some danger of infection. On the whole, cystoscopy gave the greatest help in diagnosis. In nephrectomy he preferred to cut into the parenchyma rather than the kidney pelvis, because it facilitated a more complete exploration. He doubted if a ureter could be infected by the forcible injection of fluid into the bladder.

Cholecystenterostomy in the Form of a Y.—Prof. Ambrose Monprofit of Angers read a paper on this subject. The operation, which consists in making an anastomosis between the gall-bladder and jejunum, was first performed by him in 1904. The technique is as follows: the jejunum is completely divided; the lower end is then implanted into the gall-bladder; and lastly, the upper end of the jejunum is implanted into the side of the lower end, the segments of bowel in this way assuming the form of the letter Y. He claimed that reflux of intestinal contents through the portion of gut acting as a common bile-duct was prevented. Prof. Monprofit further proposed similar procedures in relation to the common duct and the hepatic duct, to be called respectively choledochojejunostomy in Y, and hepatico-jejunostomy in Y.

SECTION OF TROPICAL DISEASES.

Wednesday, July 29—First Day.

Tropical Abscess of the Liver.—Lieut.-Colonel Sir R. Havelock Charles, I.M.S., president of the section, opened this discussion. He said he looked upon tropical liver abscess as a suppurative hepatitis due to protozoal or bacterial forms of life, the pathogenic action of which was favored by a lessened resistance on the part of the organ owing to a condition of irritation and degeneration set up by tropical conditions unsuited to the European. A study of the statistics of the relative incidence of liver abscess amongst the troops of the British and native armies in India impressed one forcibly that there must be a factor strongly antagonistic to the European soldier in distinction from his native comrade. The native soldier gave a ratio of 52 for dysentery and diarrhea, as compared to one of 35 for the same disease in his European brother. The native was 17 times less liable to hepatitis, and 25 times less liable to hepatic abscess than the European. In India in 1907 the death rate due to liver abscess had been 21 times higher amongst British troops than amongst the native army. The jail population statistics showed even more evidently the greater incidence of liver disease in the European. In five years with over 42,000 cases of dysentery there had been only 42 cases of liver abscess. What were these 42 in the 800 cases of suppurative hepatitis which had accrued during the same period amongst British troops, though here the dysentery cases numbered only 5,500? Truly some other condition than dysentery must be operative against the European lives! His argument was that: (1) The liver of the European was handicapped by tropical conditions of life. (2) The induced vulnerability was to fall a more facile victim, on its invasion by microorganisms. (3) The condition of hepatic congestion and irritation was the prime predisposing cause, whether the direct cause be protozoal or bacterial. That is the necessary antecedent of abscess must be inadequacy of the liver to cope with the work thrown on it. Amongst the conditions adversely affecting the physiological balance of liver action, he mentioned heat, food, alcohol, malaria, abuse of exercise, congestion, and inflammation. He maintained that there was a tropical liver with its special etiology as a definite disease, distinct from the congestive liver trouble of temperate climes. In criticising the relation of dysentery to liver abscess one must bear in mind that association and causation are not the same. Recent researches (Foster) pointed to the view that the ameba was not causative of acute dysentery and was only found as a rule in association with other organisms. He believed that in no case had multiplication of amebæ in absence of living bacteria been seen. They did not develop in pure cultures but in relation to bacterial symbiosis. There thus came the difficulty of explaining how an abscess of the liver which contained amebæ had arisen when no bacteria could be found therein. It was possible that in the human body in the unhealthy state, other organic substances might be able to act in the same relationship to amebæ as did bacteria, and that the bond of dysentery and liver abscess might be a contingent one, other factors determining whether the dysentery would give rise to abscess. Given a damaged liver and dysentery, then abscess would follow. Dysentery was very common among the Indian sepoys—liver complication rare. European soldiers in India suffered comparatively much less from dysentery, but very heavily from abscess of the liver. The former were careless as to drinking water. This caused dysentery, why not liver abscess? European soldiers were careful about water drinking. Amebæ swarmed in the impure waters. The liv-

er appeared immune in the one case, suffered much in the other. The liver of the European, weakened by degeneration, had in it the organic substances which help the amebæ in their onslaught. There were countries where liver abscess was fatal, but dysentery was not common (Senegal); others where dysentery was prevalent but liver abscess rare (Jamaica, Lagos); others, as in Northern Europe, where amebic dysentery was rarely followed by hepatic suppuration. Authorities differed much in assigning the proportion of cases of liver abscess associated with dysentery, and intestinal lesions did not always accompany hepatic abscess. Amebæ were commonly found in otherwise healthy people. They appeared to live, with the other fauna and flora of the bowel till some breakdown in the controlling power allowed of organisms hitherto innocuous to inflict injury on the tissues. The symptoms, physical signs, and differential characters of liver abscess were lucidly and admirably summarized by the speaker. With regard to treatment he said his practice with patients threatened with abscess of the liver had been: (1) Rest in bed, absolute; (2) external applications such as that of iodine under hot fomentations; (3) the use of sodium salicylate, ammonium chloride, sodium sulphate, iodide of potassium, ipecac, according to the case; calomel, soda, and phenalgin, not forgetting the old blue pill, followed by a saline purge, which with him, had often cured the foul tongue, the painful, enlarged liver in which pus was of a certainty thought to exist or about to form. Having established the strong probability of the presence of pus by all ordinary methods the surgeon should confirm the opinion by the aspirator, which would tell him the position, size, and direction of the abscess. He regarded the action of the aspirator as diagnostic in some cases and therapeutic in others, and practically harmless in all. Save in exceptional cases one must be prepared to operate at once in case pus be found. Generally speaking, the earlier the pus was sought for the better. Even if pus was being spat up, he thought in most cases an operation was advisable. It was of the highest importance to ensure complete drainage. It might be often a wise precaution to make one or more counter openings. The cavity should be thoroughly evacuated by altering the position of the patient. It was sometimes necessary, owing to the condition of the patient, in very large abscesses to aspirate part of the pus—making the incision a day or so later—otherwise the sudden removal of tension might be followed by fatal collapse. He never washed the interior at the operation, though at each subsequent dressing he generally passed in a douche of hot saline lotion with quinine (5 grs. to oz.). The patient never failed to express his satisfaction at the comfort given by this washing. To wait twenty-four hours before douching was good policy, he thought, from there being less chance of setting up hemorrhage. One could not use a too large caliber of drain. One thing that strongly handicapped a liver abscess case was prolonged anesthesia. It was an operation which could often be done under a local anesthetic with advantage. It was an operation also which should be done with rapidity and no dawdling. In his hospital practice although fifty-five per cent. of cases were admitted in a condition of "bad" or "very bad," employing all the usual preparatory treatment, operating quickly, without hurry and with unwearied subsequent care, his mortality was only 37.8 per cent. Private cases amongst Indians and Europeans were on quite a different footing, and gave a mortality of 20 per cent. In the prophylaxis of the disease one should regard it as preventable to a certain extent. Regarding infection of the liver as part of a general intestinal taint one should direct thorough attention to food and drink. Temperance in the use of beer and ardent spirits, the avoidance of an excessively animal diet, rich sauces, hot curries, pastries; exercising daily at suitable times. Avoiding games in the heat of the sun, which are followed by a sense of fatigue, and not the exhilaration which a healthy pastime should furnish; avoiding also excess in ice-cold drinks, during profuse sweating, and in such a condition caution in exposure to the cooling summer evening breeze, or the tempting danger of the cold bath, for, as the exhaustion of fatigue, in sun exposure, leads to hyperemia of the liver, so would the habits mentioned often further this congestion to a hepatitis. As destructive of the hurtful microorganic life one should apply the good old rule that never fails—boil the drinking water, and eat only what comes direct from the fire—cold meats that have been the disporting grounds of flies for the previous twenty-four hours should be eschewed; raw vegetables for salad, ill washed, and prepared on a foul board or floor the wise man will pass by; fruits that have no removable skin the same holds in suspicion. Some Europeans, possessing a superior heat regulating apparatus, acclimatize better than others. They bear a higher degree of temperature and a longer duration of it than those less fortunate, and are likely to be false guides to their weaker brethren.

In conclusion he said, "Pray do not apply to me the language of Milton in his 'Eikonoklastes' as to one 'who goes on building many fair and pious conclusions upon false and wicked premises, which deceive the common reader, not well discerning the antipathy of such connections.' To-day I have not an audience of common readers, but one of experts, who have discernment to see and candor enough to censure."

Dysentery with Intestinal Amebæ, but without Hepatic Abscesses.—Major A. R. S. Anderson, I.M.S., read this paper. He referred to his experience in Port Blair, Andaman Islands. During the year 1905, 2,359 cases of dysentery were admitted to the Port Blair hospitals, and of 920 of these the stools were examined microscopically. In 262 flagellates and amebæ, 4 flagellates, amebæ and *Balentidium coli*, 2 flagellates and balentidium, 1 balentidium alone. In 167 no protozoa could be discovered. The flagellates consisted of *Tamblia intestinalis*, *Trichomonas intestinalis* and *Trichomonas hominis*—the last species being most frequently encountered and constituting about 75 per cent. of the total. As control the stools, obtained by administering a watery purge to 210 patients, admitted for diseases other than those of the bowel, were examined. Of these 7 exhibited amebæ alone, 54 amebæ and flagellates and 80 flagellates alone. The larger number of the amebæ found in the cases of dysentery were no doubt those described as *Entamœba histolytica*. In the nondysenteric stools the amebæ, but for the absence of blood corpuscles from their interior, could in no way be distinguished microscopically from *Entameba histolytica*. The ameba is charged with causing dysentery because it is found in the base and surrounding tissue of dysenteric ulcers, but he thought the same charge could with greater cogency be leveled against *Trichomonas hominis*, insomuch as it is found in the same situation and occurs more frequently than the ameba in the dysenteric intestine. In his 920 cases, while ameba was found 488 times, *Trichomonas hominis* was found 540 times. Since, in Port Blair, abscess of the liver occurs in less than 1 per cent. of all cases of dysentery, or 2 per cent. of cases of dysentery with intestinal amebitis, he considered that the ameba could not be regarded as the cause of liver abscess. That amebæ are found in the interior of abscesses of the liver was undeniable, but it was a very weak argument that they cause the disease. Many observers had found flagellates accompanying amebæ in liver abscess and yet, while the ameba was incriminated, the flagellate was exonerated. He had attempted the experimental infection of animals (1 kitten, 1 puppy, 2 monkeys) with dysenteric stools containing both amebæ and *Trichomonas hominis* administered per mouth or rectum, but failed to produce either dysentery or liver abscess notwithstanding that the introduced protozoa previously absent had persisted for many weeks in the stools of the experimented animals.

In Vacca and other places in Eastern Bengal he had

found *Entameba histolytica* to be almost, though not quite, as prevalent in cases of dysentery as in Port Blair and equally dissociated from liver abscess. He believed, therefore, that *Entameba histolytica* was not an important factor in the causation of liver abscess.

Intestinal Amebiasis.—Dr. C. M. Wengle, Protozoologist to the London School of Tropical Medicine, presented this paper. He said that members of all the classes of protozoa had been found in the alimentary canal of man and to their presence had been ascribed from time to time various pathological conditions. Without denying that this might sometimes be the case, it was a fact that in many instances the only evidence for this assumption was the presence of a large and conspicuous number of protozoa in the excreta, evidence which was quite insufficient and which would incriminate at once all forms of bacteria occurring at the same time. In order to arrive at some definite idea of the intestinal protozoa he had undertaken the study of the various forms found in the intestine of white mice. All forms there met with had been described from the intestine of man, and as far as could be judged, they were all of the same species; and this was not only true of mice but also of many other animals of omnivorous habits. The advantage of studying the protozoa in the mouse was the fact that perfectly fresh material could be obtained from the various parts of the alimentary canal of the newly-killed animal. It was obviously impossible to obtain material of that kind from man. Excluding the coccidia, which had only rarely and doubtfully been described from man, the protozoa commonly met with in the intestine of mice were three flagellates and one ameba. The flagellates were Tamblia, Hexamitus, and Trichomonas. In the intestine the protozoa reproduce and multiply by a process of division. They also become encysted and the cysts thus formed pass down the intestine and escape to the exterior where they serve the transmission of the infection to a new host. In the perfectly healthy animal it was unusual to find anything but the encysted forms in the feces and then only in comparatively small numbers. Under adverse conditions, as for instance, changes in the diet of the host, large numbers of encysted forms might appear in the feces, serving to indicate that the medium had become unsuitable for the protozoa, which accordingly encysted in order to escape. The cysts were quite characteristic and by an examination of the feces it was quite possible to tell what protozoa were to be found in this intestine, in just the same way as it was possible to recognize the presence of intestinal worms by the discovery of their eggs in the stool. The only difference was that the cysts of the protozoa were small, rarely more than 14 or 15 μ in greatest length, while the eggs of worms were much larger. If the change of diet produced diarrhea it would be noticed at once that large numbers of encysted protozoa appeared in the excreta. Encysted forms might or might not be present at the same time, but the point he wished to emphasize was that the protozoa occurring in the stool were merely washed out from the intestine by the unusual flow of liquid. To any one first seeing an animal with diarrhea, and then examining and finding the stool swarming with the protozoa, it might appear quite clear that they were the exciting cause. A study of the healthy animals would enable one to avoid such an error. It would be seen that much larger numbers of protozoa could, as a rule, be found in the healthy intestine or at least the intestine which gives no indication that anything is wrong; it was quite illogical to conclude that because a large number of protozoa were present in the stool, they must be the cause of the trouble. With regard to the amebæ our knowledge of these protozoa had been very confused until Schaudinn gave his description of the two forms met with in the human intestine, one declared by him to be a harmless commensal, the other a true tissue parasite. Schaudinn not only had given morphological differences as points of distinction between the two amebæ, but he had described differences in the developmental cycle. The morphological differences were difficult to recognize and one could not be quite certain that there were not variable features in one and the same ameba. But variations in the life cycles as described by Schaudinn were definite and quite distinctive of different species. The process of development described by Schaudinn as characteristic of *Entameba coli* he had been able to confirm in almost every detail by observations on mice, monkeys, and man, but so far he had been unable to discover the reproduction by budding and the encystment of the small buds described by Schaudin in *Entameba histolytica*. The tissue-invading ameba might be a distinct form capable of attacking the tissues and causing their destruction, or it might be the harmless form which had found a path prepared for it in the way of ulceration, or what was less probable, it might be the harmless form which had acquired new properties. In stained preparations the amebæ in the tissues could not be distinguished from the harmless variety, so that unless one could discover the encystment of this tissue-invading form it would be difficult to establish the identity or otherwise of these two parasites. The ameba which was to be found in the cecum of mice was indistinguishable from that of man and certainly nonpathogenic. Musgrave and Clegg had asked how were we to tell that an intestine was perfect? Without post-mortem examination this was, of course, impossible. The study of the conditions in animals might throw much light on the subject. Here, at any rate, it could be definitely determined that amebæ did occur in the perfectly healthy intestine.

Prevention of Tropical Abscess of the Liver.—Dr. Leonard Rogers, I.M.S., presented a paper on "Tropical or Amebic Abscess of the Liver as an Early Preventable Disease, and Post-operative Sepsis as an Important Lethal Factor, with a Suggestion for Its Prevention." He first referred to a previous paper on tropical liver abscess read in 1902, when he pointed out the constancy of the presence of the ameba, which he had found in thirty-five consecutive cases by examining the scraping of the wall at the time of the operation. In two-thirds of these cases the pus was otherwise sterile on first opening, no bacteria being present. Moreover, he had shown that in over 90 per cent. of cases dysentery of the amebic type was present, although often latent in character, being only found after death from liver abscess. Last year he had pointed out that amebic hepatitis might readily be recognized in the presuppurative stage by the presence of marked leucocytosis, with little or no increase in the proportion of the polynuclears, and that it could then be rapidly cured by treating the causative amebic dysentery, of an active or, more commonly, latent nature, with full doses of ipecacuanha, and liver abscess could thus be readily prevented from forming. His results had been confirmed by Captain J. G. Murray, I.M.S., at the Calcutta European General Hospital, and by Lt.-Colonel G. F. A. Harris at the Medical College Hospital. Now he had notes of forty successful cases, proving in the most striking manner that by early negotiation and treatment of the presuppurative stage of the disease, amebic or tropical liver abscess could surely be averted. In some cases suppuration occurred very insidiously without any definite signs of acute hepatitis. These could only be detected by examination of the blood, on account of the persistent intermittent fever leading to the discovery of the form of leucocytosis already mentioned. He had recently seen two instances in which the first evidence of hepatitis was the coughing up of liver abscess pus, the blood not having been examined during the previous lengthy fever. These cases might have been amenable to ipecacuanha if recognized by the blood condition before suppuration had occurred. The British army hospitals should furnish a very favorable field for the prevention of tropical abscess of the liver, as the soldiers came under skilled treatment from the commencement of their ill-

nesses, so that this disease should greatly decrease, and practically vanish from the army returns. With regard to operation, so long as there was little or no reason to look on a tropical abscess in the liver as essentially different in its causation from other forms of suppuration, the obvious treatment was to lay it freely open and drain it. The demonstration, however, of a protozoal organism, such as the ameba, as the one constant parasite in the actively secreting wall of a liver abscess and the absence of all bacteria in the great majority of cases on their being first opened, had materially altered our conception of the pathology of the disease. The disastrous results which used sometimes to follow the opening of cold tubercular abscesses, through septic infection of the extensive lining membrane, were well known. The danger of admitting the exceedingly germ-laden air of a damp, hot tropical climate, such as that of Calcutta, to a liver abscess cavity, usually containing from half to two or three pints of sterile blood-serum-like contents, the finest culture medium for pathogenic germs which could well be conceived was not, however, sufficiently borne in mind. During the last eight years this fact had repeatedly been impressed on him, and for a long time he had been accumulating bacteriological evidence on the point, and now he considered it his duty to bring it forward in order to lessen the present great mortality after operation for liver abscess, which in Calcutta was approximately 60 per cent. His bacteriological investigations showed that although 80 per cent. of unopened or just opened liver abscesses in Calcutta were sterile as regards bacterial infection, yet in cases subsequently proving fatal, freedom from septic infection was, unfortunately, extremely rare. That the infection not infrequently did take place at the time of operation was shown by the fact that he had several times found very numerous staphylococci and, once, streptococci in addition, at the first dressing in cases in which the pus obtained at the time of the operation had been proved to be sterile. The fact that half the cases proving fatal after operation were single, or practically single, well-localized, medium-sized abscesses, and that at the time of the death of the patients they almost invariably contained very numerous septic organisms, although he had shown that four-fifths were sterile at the time of the operation, afforded reasonable grounds for thinking that post-operative sepsis was, unfortunately, a not unimportant factor in the mortality of the diseases in the tropics, and at least indicated the necessity of more strenuous efforts being made to prevent its occurrence. Our present knowledge of the pathology of the disease suggested removal of the collection of pus by aspiration, without the admission of the external air, and repeated irrigation with quinine (the soluble bihydrochloride in a strength of 3 to 5 grains to the ounce), or other ameba-destroying solutions, as the most appropriate method of treatment. The ordinary straight, stiff aspiration cannula could not be left in the cavity of the liver abscess for the purpose of repeated irrigation. He had, therefore, devised a flexible sheathed aspirator cannula, which might safely be left in and used for siphon drainage and irrigation. The fact that a single aspiration and quinine injection not rarely sufficed for the complete cure of bacteria-free amebic abscesses of the liver afforded strong grounds for believing that repeated quinine irrigation would suffice for the rapid cure of a still larger number of cases, and do away with the necessity of laying them freely open, with all the risks of that method. The aspiration method could only be used for liver abscesses with sterile contents; therefore at the first aspiration the pus removed should be at once strained and examined, and, when possible, cultures made. If numerous staphylococci were found, incision and drainage should be carried out. He was strongly of opinion that in every case in which an amebic abscess was treated surgically a course of ipecacuanha should be given as soon as the patient was in condition to stand it. Small doses, such as 5 grains three times a day, were of great value when fuller doses could not be administered, and if given in keratinized capsules or in pills coated with melted salol, as he had advised, they rarely produced vomiting, but exerted their full action on the intestines. The specific drug would not only prevent a relapse of the dysentery, which was a most serious complication after operation, but would also be effective in preventing further abscess formation. Thus an additional material reduction of mortality might be expected from the post-operative use of ipecacuanha, in addition to that already accruing from its preventive action in the presuppurative stage.

Is Dysentery the Sole Cause of the Tropical Abscess of the Liver?—Rai Dr. Koelas Ch. Bose, Bahadur, C.I.E., presented this paper. He said that on careful consideration of the various factors of the tropical abscess of the liver one might be easily influenced to give greater stress on dysentery than upon anything else. Facts and figures taken from the records of the hospitals tended to establish the relation between the two diseases. But still we often come across cases where this link was hopelessly lost. It was true that with the rise of the dysentery and diarrhea curves there was sometimes a corresponding rise in the number of admissions of hepatic abscess cases in the wards of the Calcutta hospitals. Practitioners who were not attached to a public institution, but had a fair amount of town practice, could bear testimony to it. There was a popular belief among the people of India that liver abscess was exclusively confined to persons who were intemperate in their alcoholic drink—those who do not touch alcohol being immune. Close observation proved that belief unfounded. He believed that only where the conditions of life had rendered the liver peculiarly susceptible to inflammation did dysentery become the causative agent of liver abscess. The natives of India, in all stations of life, suffered more or less from diarrhea and dysentery, but only a very small number of them suffered from suppurative hepatitis. The prisons in Bengal, in spite of all sanitary arrangements, were sometimes visited by the worst form of dysentery, which occasionally swelled the death rate among their inmates; but so far as records showed, was not accompanied or followed by abscess of the liver. From the register of the Campbell Hospital it might be found that in 1905 admissions from dysentery were 1,603, and from liver abscess only 11. In 1906 there were altogether 894 cases treated for dysentery, while admissions from liver abscess were only 9. In 1907, 1,100 patients came in for dysentery, and only 12 for liver abscess. There was not the slightest doubt, however, that the number of hepatic abscess cases among the Indians was daily increasing. The time had come when every attempt should be made to ascertain the cause of liver abscess. Granting dysentery to be a factor, it should be clearly established what variety was most potent. The amebic form possessed many advantages so far as the transmission of the pyogenic germs through the tributaries of the portal veins into the substance of the liver was concerned. The bacillary variety, which the Indians chiefly suffered from, did not possess an equal amount of facility in carrying the pyogenic germs, still it was no plea to exclude it from the list of the causative elements of suppurative hepatitis. Considering the importance of the ameba as a carrier of pyogenic germs, its existence could not be altogether ignored in the absence of dysentery, for it had often been found in the feces of healthy persons, who never in their life suffered from dysentery. It was to be regretted that both Major Rogers and Dr. Neil McLeod, who had so greatly contributed to the literature of the subject, had omitted to give a time limit to dysentery to work out its way to produce suppurative hepatitis. The mere fact of a person suffering from dysentery during infancy and then subsequently suffering from abscess of the liver when he has attained the age of fifty-five

was no good reason to infer that dysentery was the exciting cause of the abscess. Nobody knew what happened to him during the long interval of so many years; he might have suffered from enteritis, which again might have been the cause of the liver abscess. It was, he thought, absolutely dogmatic to assert that the discovery of the marks of an old cicatrix in the intestine of a man dead of liver abscess was evidence sufficient to connect the disease with dysentery. Out of 52 cases treated by him, dysentery was the causative agent in 22. In 5 it was associated with the abscess; in 7 there was ancient history of diarrhea and dysentery. In 3 it followed ischiorectal abscess; in 5 it was associated with fistula *in ano*, and in 10 there was no definite cause, and abscess was primary in the strict sense of the word. After describing those cases in which dysentery had no part to play, and in which the phases of the disease were anomalous in their character, the author discussed the diagnostic signs, the duration, the age, sex, race and season incidence, and finally the treatment of liver abscess. With regard to age, he said he had seen two cases in infants of two or three months old. One was operated on by Lt.-Col. Raye. The majority of his cases were between 20 and 45. Females were less liable than men, and it was very difficult to explain the cause. Women of the Southali, the Halkurines (Methranus) and other low-caste classes of people, such as domes, chamars, etc., did not suffer from liver abscess, although they all drank to excess. All races were liable, but the Bombay "Benies" domiciled in Calcutta did not suffer from it—at least he had not seen one within the last quarter of a century. There was no special season for tropical abscess of the liver, but the majority of cases came under observation during the advent of the cold season. January, February, and March were favorable months both for hepatic abscess and dysentery. In speaking of treatment he stated that the exhibition of ipecacuanha in large doses in the presuppurative stages had sometimes been followed by most happy results. It wonderfully stopped the suppuration and succeeded in removing fever and pain, soon restoring the unhappy patient to health. The ipecacuanha treatment was commonly known as the Maclean method of treating hepatitis. For reasons quite unexplained, this excellent method of treatment was kept in abeyance for years. To Major Rogers was due the credit of reviving it, and the results obtained were indeed very hopeful and encouraging. To understand how ipecac aborts a threatening abscess was a problem still unsolved. Large doses were decidedly better than repeated small doses. But it must be administered in a way to prevent sickness or vomiting. The combination of chloralhydrate and liquor morphiæ with the ipecac did away with vomiting.

Treatment of Abscess of the Liver by Aspiration and Injection.—Major A. Hooker, I.M.S., presented this paper. He described a case successfully treated by the method recently advocated by Dr. Leonard Rogers. Large abscesses should be opened and drained at once. Two such cases, aspirated and injected with quinine solution, both refilled and had to be opened and treated in the ordinary way. Aspiration was a procedure of long standing, as the classical works of Bud, Murchison, Morehead and Fayrer proved. It appeared to have been given up somewhat hastily in deference to the generally received surgical opinion as to the necessity of the evacuation of pus where possible by free incision. Aspiration, with the additional prospect of success held out by subsequent injection, appeared to be safe and well worthy of an extensive trial. Incision and drainage was by no means uniformly successful, and the chance of septic infection of the peritoneum was not so entirely negligible a bugbear as it was sometimes described. Attempts to suture a nonadherent liver to the abdominal wound were more often than not worse than useless.

Sir Patrick Manson, K.C.M.G., said the statistics on which the president in part based his conclusions had only a relative value. Dr. Neal Macleod had clearly shown that in Shanghai practically every case of liver abscess was preceded by dysentery, either clinically recognizable or demonstrable at post mortem. Sir Charles would have them believe that the ameba was not the essential element in liver abscess, but the position he would take was that though it had not been proved to be such, it probably was. The ordinary microorganisms of suppuration were found only in a small proportion of liver abscesses, whereas the ameba was present in the majority of cases. It was of little use looking for it in the pus withdrawn by exploratory aspirators, but if searched for in the discharge coming from the drainage tube three or four days after the operation, it was nearly sure to be found. The fact was the ameba did not live in the pus, but in the abscess wall, where it could be found in sections in the liver tissue beyond the zone of suppuration. Another striking argument in favor of the ameba was the remarkable effect of ipecacuanha both in the amebic dysentery and in dysenteric hospitals. Generally it promptly controlled both, exercising a therapeutic influence on the ameba comparable to that of quinine in malaria. Again, he had seen liver abscess rupture into the peritoneal cavity. Had the pus contained the ordinary bacteria of suppuration, septic peritonitis would have ensued. This was not the case. Drainage was followed by recovery. He felt sure that in exploring for liver abscess pus not infrequently escaped into the peritoneal cavity, explaining the pain in the lower part of the abdomen often following this little operation, but nothing further happened. The ameba did not give rise to sepsis. He wished the president had laid stress upon the extreme importance of a blood examination before exploration with the aspirator. He was sure that some of the deaths from hemorrhage following puncture of the liver were to be explained by a leucopenia. The condition would have been recognized by blood examination, and a calamity thereby averted. He recognized the advantage of local applications in inflammatory diseases, but he confessed he did not understand how the application of oleate of iodine over the right hypochondrium could influence disease in the liver, which had little or no vascular connection with the superjacent skin. Of course, he knew that therapeutics were for the most part empirical, but still they should, if possible, get at the rationale of the drugs they used.

Dr. Louis W. Sanborn said the part played by the dysenteric ameba in the causation of tropical liver abscess was evidenced not so much by the frequent association of liver abscess with dysentery as by the presence of the same organism in primary cases of both liver abscess and dysentery. Both these morbid processes might be associated or independent manifestations of the same etiological factor, just like the pulmonary and intestinal lesions of tuberculosis, but we should not forget that each one might be brought about by other agents. Thus, for example, dysentery might be due to Shiga's bacillus, to *Balentidium coli* or to *Schistosomum mansoni;* liver abscess to a needle or a fishbone, to *Bacillus tuberculosis, Echinococcus granulosus* or *Ascaris lumbricoides.* Differences in the relative prevalence of amebic and bacillary dysentery in various parts of the tropics were no doubt the cause of much of the discrepancy of opinion as to the relation of dysentery to abscess of the liver. The president had given, he thought, undue importance to climatic conditions as affecting the liver of the European in tropical countries, and had almost entirely forgotten the far more important agency of parasites. Many bacteria and certain fungi, such as *Discomyces bovis,* the Plasmodidæ, and other protozoal organisms such as *Leishmania donovani,* numerous metazoon parasites, such as *Clonorchis endemicus, Opis torchis noverca, Schistosoma Japonicum, Porocephelus armillatus,* were surely more serious causes of liver degeneration than heat, food, or

abuse of exercise. But those parasites which selected the liver for their habitat were not the only ones which might injure that organ. Many other parasites passed through it, often in great numbers, during their migrations in certain stages of development. Within the last three years he had had the opportunity of making numerous observations on the parasites of wild animals that died at the London Zoological Gardens, and the pathogenic importance of the migrations of certain metazoon parasites in their early larval stages had struck him most forcibly. He could cite numerous cases of helminths, such as ascaris, lyngamus, heterakis, esophagostomum, sclerostoma, porocephalus, and various cestode larvæ and other parasites which might pass in veritable swarms through the liver, the lungs, or the walls of the bowels, causing, especially when numerous, very serious lesions. Surely such lesions must be of great importance in favoring secondary infections. When they considered the many parasites of all classes which might attack simultaneously, or within a short period, the European suddenly transplanted to a new tropical environment, his greater vulnerability, as compared with that of the native, became obvious. With regard to the difficulty expressed by many in accepting the amebic etiology of liver abscess and dysentery, on account of the fact that the ameba is frequently found without any accompanying morbid manifestation, he would point out that although they had no satisfactory explanation apart from that of their association with other organisms, they had many analogies, such as the presence of numerous specimens of ankylostomum duodenale in the intestine without anemia, the presence of Loeffler's bacillus in the throat without diphtheria. Finally, he would like to urge the great importance of the study of the zoological distribution of the intestinal ameba. Dr. Wenyon's observations were very valuable, and he hoped that others would also carry out similar researches. Without a complete knowledge of the zoological distribution of our pathogenic parasites all attempts at prophylaxis would be futile.

Dr. F. M. Sandwitt of London said the various papers showed how deficient our knowledge was with regard to amebæ. For years we had been acquainted with the clinical symptoms of dysentery and liver abscess, and something was now known of the morbid anatomy, but we were anxiously awaiting for decisive statements from the bacteriologist and especially from the protozoologist.

Dr. J. L. Maxwell of Formosa protested against the careless use of the word hepatitis and the idea of inflammation of the liver being a direct cause of tropical abscess. That abscess of the liver might be directly caused by acute hepatitis was possible but certainly very rare. Further he asked the president about the draining of large abscesses pointing subcostally as he (Dr. Maxwell) had found proper drainage in large abscesses pointing in front almost impossible.

Dr. A. Powell of Bombay stated that he had invariably found amebæ in all cases of dysentery, both in Assam and Bombay. In Bombay during the last two years there had been hardly any amebic dysentery, but previous to that cases were more numerous. In his opinion all cases of liver abscess were associated with dysentery. He had never found flagellates in the liver. Major Anderson had found amebæ more frequently in healthy people than in dysenteric patients. Possibly the amebæ might differ in different countries. In his experience when amebæ were found the host invariably presented signs of dysentery. With regard to quinine injections Dr. Rogers had sometimes failed; it was a pity he gave no figures, his statements were vague. As regarded the treatment of the abscess, Sir Patrick Manson's method had great advantages though unsurgical.

Dr. J. Croppe of Palestine said liver abscess in Palestine was not common, but constantly present. In most cases the connection of abscess with dysentery was well marked, following the latter in so short a time as twelve days.

Dr. F. Hadley of Sheffield said in a boat returning from South Africa amongst 200 invalids there were four with heated liver abscesses. This suggested that liver abscess is perhaps more frequent after military expeditions. The good results probably were due to its not being a tropical climate.

Sir Havelock Charles, in reply, said Sir Patrick Manson thought he had not sufficiently accentuated the relationship of dysentery to liver abscess. He disagreed with this; but while admitting the strong connection between the two diseases he denied that dysentery was the sole and only cause of tropical liver abscess. Sir Patrick Manson drew his attention to the necessity of blood examination before operation for abscess lest the case were one of malarial hepatitis, but he had strongly urged not only an ordinary blood examination for malaria but also a careful blood count. Sir Patrick referred to the "old woman's" remedies of hot fomentation. He (Sir Charles) called them the "wise woman's" remedies and he maintained that they had a scientific basis by their increasing the opsonic index of the blood. Sir Patrick spoke highly about ipecac. It was a powerful drug. But on the live ameba it was harmless; a theory was requisite to help its action. Let it pass—will do as well as any other idea. He also had had recoveries, and many, too, from threatened liver abscess, by the use of other drugs. Dr. Powell stated that ever and always had he found the *Ameba histolytica* in dysentery cases in Assam and Bombay. He denied not its presence but drew attention to the able researches of Captain Foster, I.M.S., proving that (1) it was not the cause of dysentery; (2) that its presence was ever secondary to that of other organisms; (3) that there was nothing characteristic in the type of stool which might contain the ameba; (4) and that this protozoon produced no distinctive symptoms in the case. Dr. Maxwell brought forward the important point as to the possible absence of all symptoms of hepatic suppuration. But he had already spoken on that point. He considered that in the cases of abscess to which Dr. Maxwell referred, and which were large and situated upwards and backwards, as well as pointing forwards, a second aperture would be essential for drainage. Major Rogers' paper was interesting as was everything that came from his hand. He submitted for their opinion a flexible silver tube for the permanent drainage of liver abscess. That pretty instrument was an invention of the pathologist and it was fortunate that Major Rogers was dependent on others for its trial. With that instrument the bad cases would still die, and those that might recover would have lessened chances. He agreed absolutely with Major Rogers in his strictures with reference to post-operative sepsis. The after care of such cases was as important as the steps of operation. They were not students' or nurses' cases but demanded all the care that surgical skill, intuition, and technique can give.

(To be continued.)

College of Physicians of Philadelphia: Section on General Medicine.

At a stated meeting, held April 13, Dr. H. R. M. Landis read a paper, entitled, "The Complications and Sequelæ of Measles, Based on a Study of Four Hundred and Sixty Cases." The patients were observed at the Philadelphia General Hospital, the great majority occurring in children under the age of five years. Many were recent immigrants, those from Russia and Poland being principally children, while those from Italy were largely adults. The respiratory tract was the principal seat of the complications, although the circulatory apparatus and the glandular system did not escape. Bronchopneumonia was the most common cause of death. Dr. George W. Norris read a paper entitled "Lobar Pneumonia; A Study of Four Hundred and Forty-five Cases, with Especial Reference to the De-

creased Mortality Since the Institution of the Fresh-air Treatment." The cases were observed at the Philadelphia General Hospital during a period of three years, and they were compared with a larger series of cases observed at an earlier period in the same institution. Whereas the mortality in the latter was upward of 50 per cent., that among the former was rather less than 50 per cent., but although the difference in mortality was not considerable, the patients themselves appeared so much more comfortable under the new conditions that the conviction could not be escaped that they actually did better.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

RELIGION AND MEDICINE. By ELWOOD WORCESTER, D.D., Ph.D., SAMUEL MCCOMB, M.A., D.D., and ISADOR H. CORIAT, M.D. 12mo, 428 pages, illustrated, cloth; $1.50 net. Moffat, Yard and Company, New York.

MEAT AND FOOD INSPECTION. By WM. ROBERTSON, M.D., D.P.H.F.P.S. 8vo, 372 pages, cloth, illustrated; $3.50 net. W. T. Keener & Company, Chicago.

THE HEART AND SUDDEN DEATH. By THEODORE FISHER, M.D., F.R.C.P. 12mo, 53 pages, illustrated, paper. The Scientific Press, Ltd., London.

OUTLINES OF PHYSIOLOGY. By EDW. GROVES JONES, A.B., M.D., and ROBT. GRIER STEPHENS, A.B., M.D. 12mo, 383 pages, illustrated, cloth; $1.50 net. P. Blakiston's Son & Co., Philadelphia.

PHARMACOLOGY. By MAURICE VEJUX TYRODE, M.D. 8vo. 255 pages, cloth; $1.50 net. P. Blakiston's Son & Co., Philadelphia.

THE PATHOLOGY OF THE EYE. By J. HERBERT PARSONS. Royal 8vo, 1427 pages, cloth, illustrated; $3.50 net. G. P. Putnam's Sons, New York.

SEX OF OFFSPRING. By FRANK KRAFT, M.D. 12mo, 112 pages, cloth. B. Barsuette, Cleveland, Ohio.

ZUR DIAGNOSE UND THERAPIE DER NIEREN-BLASENTUBERKULOSE bei der Frau. Von Dr. R. KNORR. 8vo, 48 pages, paper; 8 Mark. Carl Marhold, Berlin.

MODERN MEDICINE. By WILLIAM OSLER, M.D. Royal 8vo, 866 pages, illustrated, cloth. Lea & Febiger, Philadelphia.

UROGENITAL THERAPEUTICS. By FILIPP KREISSL, M.D. 8vo, 461 pages, illustrated, cloth; $5.00. Cleveland Press, Chicago.

DIE LEHRE VON DER INTUBATION. By Prof. Dr. J. VON BOKAY. 4to, 250 pages, paper, illustrated. 10 Mk. F. C. W. Vogel, Leipsig.

THE PRACTICAL MEDICINE SERIES (Vol. I.). By GUSTAVUS P. HEAD, M.D. 12mo, 406 pages, cloth, illustrated; $1.50. The Year Book Publishers, Chicago.

THE PRACTICAL MEDICINE SERIES (Vol. II.). By GUSTAVUS P. HEAD, M.D. 12mo, 614 pages, cloth, illustrated; $2.00. The Year Book Publishers, Chicago.

LEHRBUCH DER OHRENHEILKUNDE FÜR STUDIERENDE UND AERZTE. Von Dr. GEORG BOENNINGHAUS. 4to. 378 pages, illustrated, paper. S. Karger, Berlin.

CONSULTATIONS. By H. STAPFER. 4to, 501 pages, paper. Vigot Frères, Paris.

LES EUNUQUES À TRAVERS LES ÂGES. Par Dr. RICHARD MILLANT. 12mo. 205 pages, paper, illustrated. Vigot Frères, Paris.

THE OPSONIC METHOD OF TREATMENT. By R. W. ALLEN, M.B., B.S. (London). Octavo, 136 pages, cloth; $1.50 net. P. Blakiston's Son & Co., Philadelphia.

THE MOTHER'S YEAR-BOOK. By MARION FOSTER WASHBURNE. 12mo, 259 pages; cloth; $1.25 net. The Macmillan Company, New York.

THE DEVELOPMENT OF OPHTHALMOLOGY IN AMERICA, 1800 to 1870. By ALVIN A. HUBBELL, M.D., Ph.D. 12mo, 107 pages. Cloth, illustrated, $1.75. W. T. Keener & Co., Chicago.

LA DIATHÈSE URIQUE. By HENRI LABBÉ. 12mo. 95 pages; paper, 1 fr. 50. J. B. Bailliere & Fils.

THE SEXUAL QUESTION. By AUGUST FOREL, M.D., Ph.D., LL.D. 8vo, 536 pages. Cloth, illustrated. Rebman Company, New York.

NEWSPAPER DIRECTORY AND ADVERTISERS' MANUAL, 1907. 16mo, 656 pages; leather. The George M. Savage Advertising Agency, Detroit.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City for the week ending August 15, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	443	160
Diphtheria	134	11
Measles	106	5
Scarlet Fever	87	7
Smallpox	—	—
Varicella	9	—
Typhoid Fever	124	17
Whooping Cough	18	5
Cerebrospinal Meningitis	5	7
Malarial Fever	—	—
Totals	926	212

Tincture of Iodine in Puerperal Fever.—Aldo Mergari describes his method of using tincture of iodine for the differential diagnosis between syphilis and tuberculosis seven cases with marked success, the improvement being manifested in a single day after treatment was begun. He washes out the vagina and uterus with antiseptics, curettes when it is necessary to remove placental fragments, and then injects through a Doleris sound from 100 to 150 grams of equal parts of tincture of iodine and water. This is allowed to flow out as soon as any pain is felt, and the excess is washed away with boiled water. No tampons are used. The author ascribes the good results to the large amount of normal iodine that enters the uterus.—*La Riforma Medica.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service for the week ending August 14, 1908:

		CASES.	DEATHS.

PLAGUE; MODE OF DISSEMINATION AND METHODS FOR CONTROL.*

BY J. C. PERRY, M.D.

SURGEON, P. H. AND M. H. S., CHIEF QUARANTINE OFFICER, ISTHMIAN CANAL COMMISSION, ANCON, C. Z.

IT is not my intention to present a monograph on plague, dealing with the various clinical phases of the disease and the pathological changes that occur, but only to call attention to the symptoms and morbid changes to a sufficient extent to make my meaning clear and to form a proper connecting chain with the more important intents of this paper—the mode of dissemination of the disease and the proper remedial measures to be instituted for its control.

Plague is a disease of vital importance to the sanitarian and I trust of sufficient interest to the clinician to warrant a brief discussion of this subject. It seems to me that the time is opportune for the presentation of recent findings concerning the disease which I have been able to glean from recent literature together with that acquired from practical experience.

The Isthmus occupies the unique position of one of constant exposure and at the same time one of strategic importance. Our ports on the Pacific have been in constant commercial relation with plague-infected ports for the past four years. Each year the disease in its insidious approach has crept nearer, so that now we have a severe epidemic prevailing in Guayaquil only three days distant, and in the past two months our danger has been still further increased by the appearance of the disease in La Guayra, only three days from our important commercial port, Colon.

A moment's consideration will show the strategic position, because, if our ports can be kept free from the disease or are in such a sanitary condition that if infection gains an entrance, the disease will not become endemic or epidemic, the chain of Central American ports both on the Atlantic and Pacific will in all probability escape; on the other hand if our ports become badly infected the places mentioned will almost certainly fall, and not being properly equipped to handle such infection, they would remain a constant menace to the Isthmus after the eradication of the disease here. It is to show how this danger may possibly be avoided and if it should become an actual fact, how it can be eliminated, that this paper is presented.

A brief reference to the history of plague may not be amiss, especially that part which relates to the wide dissemination of the disease since its reappearance in 1894.

The description of plague handed down from ancient times is rather vague and epidemics bearing this name were probably not all of the disease under consideration. In fact the name plague was loosely used and apparently referred to any epidemic disease accompanied with a high mortality. The first authentic description recognizable as plague refers to an epidemic that prevailed in Egypt and neighboring countries at the end of the third century. Egypt in early days was a favorite haunt for the disease and in this country started the epidemic of 542 that lasted sixty years and spread over Europe with frightful devastation. Probably the best known of the early epidemics is that which prevailed in London in 1664 and 1665 and caused 70,000 deaths.

This now brings us to the consideration of the present epidemic that is slowly invading many countries of the world. Plague had been endemic in Southwestern China for many years and in the Spring of 1894 spread to Canton, where it caused 60,000 deaths during that year. In a few months Hong Kong became infected and suffered from a severe epidemic. The disease spread from Hong Kong to Macao, Amoy, Foo Chow, and other ports in China. It was while studying this disease in Hong Kong in 1894 that Kitasato and Yersin working independently discovered the bacillus pestis. A few cases of the disease were reported in Hong Kong during the following year, and it reappeared in 1896 with the resultant severe epidemic, and during this year was introduced into Bombay, India, in all probability through an infected cargo of rice. The infection has remained in these places ever since, and in India the yearly epidemics have resulted in frightful loss of life.

In 1899 plague gained an entrance into Japan, the Philippine Islands, Egypt and Oporto. Early the succeeding year some ports in Australia became infected. In the meantime the disease approached the Western coast of the United States, by the infection of Honolulu and early in 1900 was present in San Francisco. Glasgow became infected in 1901. About this time (1900) the disease gained an entrance into South America, the ports of Brazil becoming infected and later cases appeared in Buenos Aires. Mazatlan had a sharp epidemic in the fall of 1902, and plague was reported in Peru and Chile in 1903. Ecuador escaped until February, 1908, but is now suffering from a severe epidemic. The disease has been in Mauritius, Cape Town, and other ports of South Africa for several years. From the above it will be seen how the slow spread of the disease, starting from the epidemic of Hong Kong in 1894, is gradually invading a large part of the world. Where and when will it stop; who knows?

Symptoms.—The importance of recognizing first cases of plague, before the disease has been reported as present, is of such paramount importance that brief mention of the symptoms of the disease is proper. The value of alertness and careful diagnosis in all cases that present any suspicious symptoms in a town threatened with plague cannot be

*Read before the Canal Zone Medical Association, May 13, 1908.

overestimated. The bubo may pass as a simple one, especially if the person should recover, and pneumonic plague might be considered an ordinary bronchopneumonia of unusual severity unless the attending physician is alert to the possibility of having to deal with plague. This word of warning is not amiss, as what has been stated above is what generally occurs in the first stages of epidemics of this disease. The great value of determining the exact nature of such cases is apparent, because if the first cases are detected immediate sanitary measures can be instituted and the limited foci of infection may be eradicated and an epidemic prevented.

The bubonic type of this disease is the most frequent and is generally ushered in suddenly with chilly sensations, severe frontal headache and pain in the limbs, rapid rise of fever to 102° or 104° or higher (although the rise in temperature is not so sudden as in malarial fever). The skin is dry and hot, the face is congested, anxious, and often looks bloated in the early stages; the eyes are sunken and bloodshot. The strength of the pulse is early affected, and the patient becomes rapidly prostrated, dull, apathetic, and often delirious. Hemorrhages occur in the skin in spots varying in size from a petechial eruption to that of a dime or larger. I have often noticed the effects produced by a mustard plaster applied by a member of the family for pain; this, even early in the disease, and before cutaneous hemorrhages occur, almost invariably brings about this condition and there results a dark ecchymotic spot the size of the plaster.

The bubo is generally present and can be detected in the majority of cases after twenty-four hours, although I have seen them in a few hours after the onset or delayed until the fourth day of the disease. They are painful, infiltrated, edematous, hemorrhagic, and exquisitely sensitive on pressure; it is generally confined to one side and may be single, although very often the entire chain is involved so that a long infiltrated mass results.

The site of the bubo depends on the point at which the infection is received. They are most common in the femoral regions because infection is most often received through the lower extremities, but also occur in the axilla and the neck, near the angle of the jaw. They are symptomatic and represent nature's effort to control the infective agent. The following percentages generally hold good: 70 femoral, 20 axillary, and 10 cervical.

Septicemic Form.—In this variety most of the symptoms already enumerated are present, although the fever is not as high in many cases. The bubo is later in appearing, and is frequently absent altogether. The prostration is more pronounced and the disease runs a more rapid course. In this form when no bubo is visible there is general glandular enlargement noticeable on post-mortem examinations.

Pneumonic Type.—This is the most dangerous form of the disease, but fortunately is rare on the Pacific Coast. In this connection only the primary pneumonic form will be considered as that secondary to general plague infection of other types needs no especial mention. Unless plague is known to be present a case of this disease might be mistaken for a very severe pneumonia, as the physical signs are the same as those of a severe case of bronchopneumonia. However, the fever is high, the prostration is profound and occurs early, and the sputum is not pneumonic. The expectoration in plague pneumonia is profuse, bloody, frothy, and so loaded with plague bacilli that it is often possible to obtain pure cultures from it.

The symptoms of plague are sufficiently distinct to excite suspicion when a case of either type is encountered, and a bacteriological examination of the blood in the bubonic and septicemic form and of the sputum in pneumonic cases will remove all doubt for practical purposes.

The percentage of the different forms of plague in an epidemic seems to vary considerably in different countries. In Hong Kong in an analysis of 310 cases by Simpson 40 per cent. were septicemic and 4 per cent. pneumonic. Judging from the death rate from the disease in India it is fair to presume that the percentage of septicemic cases is high with more than the average number of cases of the pneumonic form.

On the Pacific Coast, in Peru and Guayaquil, the disease is principally bubonic, and I do not believe that the septicemic form exceeds ten or fifteen per cent. Pneumonic plague is not frequent on the coast and with the exception of the epidemic in Pisagua I believe the number of cases have been relatively small.

Pathology.—The pathological changes in plague are those of engorgement and hemorrhage. The liver is congested and the spleen shows a similar condition and is more than twice its normal size. Numerous punctate hemorrhages are seen on all the serous surfaces, and the pleural cavities often contain blood stained fluid. The kidneys are congested and punctate hemorrhages are seen on the surface and in the pelvis. The mucous membrane of the intestines shows general congestion, and I have seen in some cases considerable hemorrhages in the lumbar region. There is general enlargement of the lymphatic glands, those in the inguinal region forming a continuous chain in extension from the primary bubo in the femoral region. The mesenteric glands are nearly always enlarged, and this general affection of the internal glands is present when no primary visible bubo has existed. The gross changes are those of hyperplasia of the gland tissue with edema and hemorrhages in its substance. Most of the buboes undergo resolution, but suppuration is not uncommon, which prolongs the convalescence. The plague bacillus, a cocco bacillus which stains in a bipolar manner, exists in abundance in the enlarged glands, spleen, liver, and blood. This bacillus varies considerably and involution forms are common.

Treatment.—The medicinal treatment of plague is supportive and stimulative, and about the only remedy that produced good results is Yersin's serum. This to be effective should be given early and in full doses. An initial dose of thirty or fifty cubic centimeters should be given, to be followed in a few hours by another or a third until there is a decline of the fever and general amelioration of the symptoms. The serum to be beneficial must be given early and upon the stage at which the patient is put under treatment will depend its success. After the third day of the disease it does little if any good.

The ravages of plague are in some instances frightful. In the small town of Pisagua the deaths occurred so rapidly that there were not enough well people to bury the dead and dead bodies were seen lying in most of the streets. In Pacasmayo, a small town in Peru of 2,000 inhabitants, there were more than 200 cases in less than two months, and in Guayaquil there were nearly 500 cases in the first two months of the epidemic.

However, India furnishes the best example of the

ravages of this disease, as the following statistics will show. The annual mortality from plague in India has been as follows (Morehead):

1896.....	1,704	1902.....	577,000
1897.....	56,000	1903.....	850,000
1898.....	118,000	1904.....	1,022,000
1899.....	135,000	1905.....	951,000
1900.....	93,000	1906.....	332,000
1901.....	274,000		

(Nov. 24, 1906, to Nov. 9, 1907, 1,276,576)

During the first three months of this year the mortality has been about 495,000, and the total deaths since its first appearance has been as much as five and one-fourth millions, with a mortality as high as 76,000 in one week.

Modes of Dissemination.—In discussing the modes of dissemination it will be proper to consider the subject under two heads—(1) the introduction into a new port or town, and (2) the means by which it is spread in the town from its infected foci and to adjacent towns. Plague, when it is introduced into a new country, practically always appears in the seaport towns first, which shows the danger to be primarily in the commercial relation which the place has with infected ports.

(1) The introduction of plague in a new country or port occurs through infective material brought and the following agencies are responsible. I mention them in the order of their danger and responsibility: (*a*) Rats, (*b*) Infected cargo, (*c*) Infected clothing of passengers and crew of ships, and (*d*) Infected persons. These agents will now be considered separately and fully—

Rats.—There is no question in my mind but that these animals are the most potent factor in introducing plague in new places. Rats gain access to ships at infected ports and going on shore at ports of arrival communicate the disease to the same animals in their new locality, thereby starting the infection. Plague is primarily a rat disease, and an epizootic affection in all the rat family. The disease is secondary in man, as continuous observation has shown that plague exists in rats before human cases appear. Rat-plague should be treated by the sanitarian the same as human plague, but this phase of the disease will be discussed more fully later.

Infected Cargo.—Certain articles of cargo that have become infected in centers in which plague prevails either by serving as rat-foods or as a nesting place for these animals, becoming infected by the secretion or excretions of sick rats or harboring fleas from such, must be considered as the second most dangerous factor in introducing plague. In this class fall grain, bran, etc. Klein has shown by experiments that he was able to transmit plague to rats and guinea pigs by feeding them with grain which had been contaminated with old plague cultures, so there would seem to be no doubt of this danger. In fact I have always considered this danger and for the past four years all such cargo has been prohibited from being brought from plague-infected ports to those on the Isthmus. This grain which has been infected from sick rats when loaded and stored in healthy seaports gives plague to healthy rats on shore, which eat the contaminated portions of the grain or through fleas harbored. As already stated, plague is supposed to have been introduced into Bombay by infected rice.

Another article of cargo is hides, which by forming nesting places for rats, or rat food when damp or improperly cured, are in the prohibited list unless chemically cured and stored in rat-proof warehouses or disinfected. Rags or loose cotton and articles of such nature are dangerous, and plague was in all probability introduced into Japan through such cargo, as the first cases occurred in a factory at Osaka where such material recently imported from New Chang was being used. The first cases of plague in Glasgow occurred among rag pickers.

Clothing of Persons.—Clean, dry, and recently laundried clothing is safe: soiled, dirty, and damp clothing brought by passengers coming from plague-infected ports is not safe, unless previously disinfected, and may be the means of introducing infection. This clothing has often been in badly infected quarters and even used at times by the sick, and when packed in such places may be both infected with plague bacilli and infested with fleas, and bedbugs which will transmit the disease to rats and man, when set free in their new residence. Soiled, damp clothing when packed will retain plague infection for a considerable time.

Infected Persons.—Man plays a subordinate role in the introduction of plague or even in its spread, but nevertheless he must be considered a factor, as some may arrive who are suffering from the active disease and others in the incubation stage. Against introduction by this means the quarantine should protect, but in the event of a prolonged stage of incubation or for other reasons a person sick from the disease is allowed to pass into a healthy town he would be dangerous to the community not only on account of the infection but also because he carries the rat flea on his body and in his clothes. This flea finds its way to its natural host, so that the rats become infected and in turn give the disease to man.

Spread in Towns.—This now brings us to the consideration of the modes of dissemination in towns that have received infection. The agencies that produced the initial focus are also operative here, but one or two of those factors play an especially prominent part. Rats and the fleas they harbor are the important agents. Rats become infected first and an epidemic prevails in them before the occurrence of human cases. So certain is it that human cases will follow plague in rats that now as soon as it is proven that these rodents are dying from plague active sanitary measures are taken with excellent results.

Plague is insidious in its approach and spreads slowly at first. In San Francisco it was confined to Chinatown for four years, and one explanation of the recurrence of the diseases in 1907, was that after the earthquake, with the burning of Chinatown, the rats suffering from chronic plague fled to other and all parts of the city, especially to places of filth and plenty of food, which ideal conditions were found in the two principal camps for refugees. Around the site of these camps the worst centers of the epidemic existed, and the disease was widely disseminated throughout the city.

In Bombay the disease was for some time confined to one section of the city, a class of day laborers and their families residing in this section being the only ones affected. Although the laborers during their work were in close relation with others, none had the disease, showing that they contracted the infection at night by sleeping in an infected environment.

When plague appears in a place and a number of cases result in a short period of time the people become panic-stricken and flee to healthy towns—no cordon will prevent them; still very little if any plague occurs along the route of their flight, and it is not until later, when the rats migrate to escape the sickness prevailing in their old haunts,

that spread of the plague occurs. It has been noticed a number of times that the spread of plague has not followed the course taken by people but occurs in towns corresponding to the direction the rats have gone.

This now brings up for consideration how the disease is transmitted from rat to rat, and as it has been shown that plague in these animals precedes human cases, how plague is acquired by man and if the disease is transmitted from rats to him.

Fleas.—Symond was one of the first to show that rats acquired the disease from each other, not by contact, but through an intermediary host, which he considered the rat flea, *Pulex cheopis*. He also believed that this insect was responsible for plague in the human subject, leaving the rat dead from plague for man, thereby infecting him. This theory was supported by Thompson of Sydney, who has done considerable work along this line in his plague investigations in Australia. Most important experiments have been made by the Indian Plague Commission, which supports this theory, and I cannot do better than quote some of their findings.*

1. They found that healthy rats contracted plague by living near a plague-infected rat, where contact was impossible, but where there was an abundant supply of fleas that could pass freely from rat to rat.

2. Healthy rats living in flea-proof cages contracted the plague when fleas collected from a rat, suffering from plague in another cage, were introduced.

These two experiments show that plague is transmitted from one rat to another by fleas. Similar experiments have been carried out with guinea-pigs with the same result. When fleas were excluded these animals did not contract plague although they were in contact with feces and urine from infected animals. Close contact of the young, even when suckled by plague infected mothers, did not give the disease to the former.

If fleas are present then the disease once started spreads from animal to animal, the rate of progress being in direct ratio with the number of fleas present. Through the agency of the flea plague can be transmitted not only from rat to rat but also from rat to guinea-pig and vice versa, also from guinea-pig to monkey.

It was shown that infection could take place without any contact with contaminated soil. Guinea-pigs were placed in a cage two inches above the floor and developed plague, but when these animals were suspended in the cage at a distance of two feet from the bottom of the cage, at a distance beyond which a flea can jump, they remained healthy.

The rat flea prefers a guinea-pig to man, but if neither of these animals are present they will attack man. Advantage has been taken of the fact that guinea-pigs will collect such fleas by placing them in houses in which plague has occurred, and which have been disinfected and vacated, in order to determine whether such houses are safe to be occupied. In many such instances the pigs have taken sick and died from plague, collecting fleas in large numbers, thereby showing that the disinfection has been ineffective by not killing the fleas that have taken refuge in the cracks of the floor and under sand.

Rats attack and devour sick and dead rats and this constitutes a minor way in which plague is transmitted among these animals.

*Many of the experiments cited are quoted from Major Morehead's article, "Plague in India," in the *Military Surgeon*, March, 1908.

The next point to be considered is—will rat fleas bite man? That they will has been proven by experiments, and if plentiful will even do so in the presence of their natural host. They have been kept alive for more than three weeks by feeding them on man, also rat fleas have been found on the legs of men sent into rooms infested with them as well as when sent in houses in which plague had occurred.

It having been established that such fleas will bite man, how is the infection transmitted? The plague bacilli are contained in the blood they suck in, and they have been demonstrated in the stomach and intestines of both rat and human fleas. Multiplication of bacilli takes place in the stomach of the flea and they have sometimes been found in the esophagus, but nowhere else in the body cavity or salivary glands. The bacilli also exist in the feces of fleas taken from plague rats.

The flea has the nasty habit of squirting blood from its intestine at the same time it is sucking in blood, and as such contains bacilli, infection probably occurs by scratching and rubbing such discharged contents into the small punctate wound made by the bites.

Rat fleas leave the dead animal, and being in a starving condition readily assail man or animal and convey the disease to their new host. It has been noticed that persons who handle rats recently dead of plague contract the disease, while others can handle such rats that have been dead several hours without much risk. The explanation is simple: If the rat has just died the fleas are still on it and pass to the person handling, whereas in the other case the fleas have already left the dead body.

I have discussed freely the relation of rat to human plague and the method of transmission from the rat to man by the flea, as it represents the most recent as well as the most important work done concerning the dissemination and transmission of the disease.

While most cases of plague of the bubonic type are contracted in this manner, many authorities will not admit it is the method of infection in septicemic plague and think many cases of the bubonic form are contracted in other ways. We know that plague is inoculable, unfortunately there have been too many laboratory accidents that prove this, and I cannot see why a certain percentage of cases may not be due to persons with abrasions on their body contracting the disease by coming in contact with infective material.

Food.—If food products contaminated with the infective agent of plague will produce the disease in rats by them eating the same, it is reasonable to suppose that this might occur in man to a certain extent. Simpson is the strongest advocate of this and believes that septicemic plague is generally contracted in this manner. It is not difficult to see how an infection of cooked food might occur, especially from the excretion of plague rats, and it seems possible that the ingestion of such food might produce the disease.

Man.—Persons are secondary to rats in the spread of plague, but nevertheless they form a factor that should receive due consideration. Persons exposed to infection often contract the disease and proceed to new and healthy localities either with the active disease or with it in the incubation stage. While they are a menace to the community, their principal danger consists in the fact that they carry their clothes and often bedding, which if not soiled with the plague bacilli, generally contain fleas which, liberated in the new place, seek their natural host and start the disease among the rats.

In pneumonic plague man is an important factor as he contracts plague by contact, by inhaling the bacilli that exist in abundance in the small particles of expectoration that are in the air.

Season.—This is probably a good place to refer to the seasonable prevalence of plague and the most plausible explanations given for this characteristic. In India the plague lies dormant during the winter months, but appears in the spring, reaching its height during March and April. In Hong Kong the disease appears in January or February and increases until June or early July, when the epidemic reaches its height, then declining until few if any cases are reported during October, November and December. In Peru the seasonal increase in plague corresponds closely to what occurs in Hong Kong. Manila furnished a similar example.

There is a cause for this seasonal prevalence which has been sought by numerous investigators. For a long time it was thought that the plague bacillus lay dormant in the dirty floors or filth in the plague houses and the advent of plague the next season was due to increased virulence of these bacilli. This theory has been disproved. The Indian Plague Commission has shown that the bacilli soon die under such conditions, that plague bacilli are unable to live a saprophytic existence, and that the living tissues and blood of the rat are necessary for their propagation.

Plague exists in a chronic form in rats, the bacteria being encapsulated in the viscera, the cervical and the inguinal glands. These rats have been found alive, emaciated or not, but still ambulatory foci for the spread of the infection The virulence of organisms recovered from such rats has been demonstrated by laboratory experiments in San Francisco. This seems to be the principal cause of the continuance of the infection and the long intermission between cases.

As the seasonal increase of plague corresponds to the time when fleas breed and a new generation of rats susceptible to plague appears, it can readily be understood that with the chronic plague rats to furnish the foci of infection a fresh outbreak occurs among these animals with consequent increase in the number of human cases. The above is now considered the probable cause of seasonal prevalence.

Prevention of Plague Infection, Eradication of the Same and Control of Epidemics.—In the first place I wish to emphasize the importance of prophylaxis in all ports and towns, which from their commercial relations with nearby centers of infection, are threatened with invasion. Under this heading will be pointed out the preparatory sanitation of places from a plague standpoint, which enumerated briefly are: (1) rat destruction; (2) making houses rat-proof as far as possible, by remedying defects in construction so that rats cannnot gain access to buildings and by changes so that dark and illy ventilated compartments are freely opened to sunlight and air — both of which are inimical to rats and fleas; (3) by cleaning premises and attention to stables so that rats will not have places for harboring and for obtaining food. Wherever you have filth and food there you will find rats and fleas in abundance.

Another matter I wish to emphasize is that a careful watch should be maintained over mortality in rats, if any number is found dead in a locality, these dead rats should at once be examined pathologically and bacteriologically in order to determine whether they are plague infected. If this examination is positive, plague infection is present and human cases will soon follow unless the most energetic measures are instituted. Rat plague requires the same sanitary treatment as human plague, and following this timely warning prompt and energetic measures may prevent an epidemic and lead to eradication of the infection, especially if the town has been prepared as outlined above to meet the invasion.

The early recognition of human cases is also important and all that are in any way suspicious should be carefully studied both clinically and bacteriologically. Upon prompt recognition of plague whether in rats or man will depend success in controlling the infection.

The sequence of events in a newly infected place is: dead rats found in the houses or sick rats appearing in the daylight, then cases of plague occurring in the persons that live in houses in which dead rats have been found.

As this paper is growing longer than I intended I will not go into the details of quarantine methods by which plague is prevented from gaining access to healthy ports, but only briefly mention what are proper. They are as follows: (1) Fumigation of ships to destroy rats. (2) Prohibition of such cargo as is considered unsafe from a rat standpoint. (3) Disinfection of baggage of passengers embarking at plague-infected ports. (4) Examination of the personnel of the ship both at port of departure and at that of arrival to detect persons sick from the disease. (5) The quarantine detention of the personnel of the ship to cover the incubation period of plague.

Control of the Disease in Infected Centers.—To control the disease or eradicate the infection the same general principles appertain whether there are one or many foci, the methods being amplified to meet the conditions.

A working organization should be perfected and the town or city divided into as many districts as the situation demands, with a competent director in charge. Upon the occurrence of a case of plague in a block or district, one should ascertain if possible the source of infection and attempt to eradicate it by concentrating a sufficient force to carry out the necessary measures in the shortest possible time. All cases of the disease should be removed to an isolation hospital, and when this has been done the house in which the sickness appeared should be immediately disinfected. The most efficient method is as follows: burn four (4) pounds of sulphur to one thousand (1,000) cubic feet of air space after carefully sealing the rooms. Twelve hours exposure should be given. This fumigation destroys vermin, and sulphur is the best agent to use. Formaldehyde does not kill insects. All articles in the house or rooms should be carefully disinfected. Old clothes, bedding, and other articles, infected by excretions from the patient should be burned. Carpets and rugs should receive careful attention and all sweepings should be burned. The floors and walls, especially that portion adjacent to the floors, cracks, and crevices should be washed down with a strong bichloride of mercury or carbolic acid solution.

In my work at La Boca, Panama, in 1905, all houses were first fumigated by burning sulphur and then immediately disinfected by washing all the walls and floors with strong bichloride of mercury solution. I consider this second disinfection even more important than the first.

Especial attention should be given to the block in which the case has occurred and the most energetic measures should be immediately instituted to sanitate the district. At the same time attention

should be directed to contiguous blocks and their sanitary condition should be carefully noted. Inquiry should be made concerning sickness in the district in order to determine whether any suspicious illness exists or has existed during the past few weeks. A careful examination should be carried out of the general sanitary condition of the district and an inspection of premises should be made to determine their cleanliness or otherwise, the presence of stables and old dilapidated outhouses where rats could harbor and breed, the presence of rat runs and these rodents, and whether on account of food, etc., the conditions are favorable for the existence of rats in numbers. It is especially important to ascertain if sick or dead rats have been seen.

Rat holes and runs in the infected and adjoining buildings should receive careful attention and be satisfactorily closed whenever practicable. It is also advisable to flush such places with strong carbolic or bichloride of mercury solution.

Poison, arsenic and phosphorous paste, and traps should be distributed throughout the district to destroy rats, and these measures should be supplemented by a free use of the different rat viruses that produce a transmissible fatal disease in these rodents.

Attention has already been called to the importance of rat destruction and when infection is present this measure is of paramount importance. However this is difficult to execute, and even after thousands of these animals have been destroyed little appreciable difference in their numbers is noticed. In Tokyo, Japan, where the most favorable results have been obtained with this measure, after five million rats had been destroyed, still the daily catch was large. It seems that depletion in the ranks of the rat family lessens the struggle for existence and favors increased reproduction. The morbidity and mortality rate from plague in rats is frequently low, and this renders the work of eradication of the disease more difficult, since if it spread rapidly among rats they would soon be exterminated and the chief source of infection to human beings would cease. In Hong Kong the number of infected rats is about seven per cent. of the total number examined, and in San Francisco it has been less than one per cent. (Blue).

This measure, however, should be pushed with vigor, and coincident with actual destruction of rats by trapping, poison, etc., the general sanitary procedures to destroy their haunts and breeding places by rendering houses rat proof; general cleaning of yards, attention to stables, destruction of old structures and the liming of outhouses and premises, and destruction of rat runs, with attention to the sewers, should be carried out as rapidly and thoroughly as possible. These general sanitary measures affecting the houses and premises will do more toward exterminating rats than anything else, but unfortunately it is slow of execution.

Evacuation.—The second important measure in the control of plague is the depopulation of infected centers and the destruction of badly infected buildings. This has been effective in several instances in the epidemic in San Francisco in stopping the march of the disease, and is recognized in India as the most important measure to carry out.

This applies not only to houses in which human cases have occurred but also to those in which rats have died from plague, and in this connection it may be stated that houses and premises in which rats dead from plague have been found should be subjected to the same careful disinfection and cleaning as if the case had been in man.

When plague has once occurred in a house there is a great tendency in subsequent years for the disease to appear in this or the adjacent houses. This may be accounted for by the lack of protection against the ingress of rats, and when this defect has been remedied the disease will not reappear.

If infection continues in such houses after careful disinfection, and they cannot be made sanitary from a rat standpoint, they should be destroyed, as such are generally old, dilapidated, and of little value.

Inoculation.—This must now be recognized as one of our most potent factors in controlling an epidemic. Recent results show the value of this practice and it is now much more extensively used than a few years ago. If such an inoculation protects for six months or a year, and it can be carried out on a large scale, thereby lessening materially the number of susceptible beings, its use in plague epidemics will be a capable weapon in our hands.

Two methods are practised: One is the use of Yersin's antitoxic serum (10 c.c. dose); this confers only a transient immunity, lasting about fourteen days; the serum is applicable to contacts, as Haffkine's fluid, a toxin, would be dangerous on account of the possibility of the person already suffering from plague in the incubation stage.

In the other, Haffkine's fluid, which is a bouillon culture in which the bacilli of plague have been killed by heat, is used. These antiplague inoculations have been extensively practised and there remains the possibility of immunizing all persons in the infected district against the disease. Numerous observers confirm the value of this inoculation, and Haffkine claims that, even in natives of India who are very susceptible to plague, the liability to attack is lessened to less than one-third, and that when this one-third contract plague the recovery rate is double that in noninoculated natives. The degree of protection afforded Europeans is even higher, and Haffkine says that if one of this class that has been inoculated is subsequently attacked with plague he has generally recovered.

In Guayaquil more than 15,000 persons have been inoculated, some with Haffkine alone and others with a primary inoculation of Yersin's serum followed by Haffkine's. It is too early to secure accurate statistics, but one or two striking instances reported to me by private letter by Lloyd will be mentioned: Of fifty workmen, who were in a badly infected place, forty-nine were inoculated, the fiftieth man refused and died of plague. The disease did not occur among the others. About eighty workmen in a brewery were inoculated with Haffkine, one man who lived under better conditions refused; he contracted plague and died; so far all the others have escaped. These may be coincidences, or rather suggestive facts; I believe the latter.

Dr. Lloyd informs me that he has seen six persons who had plague after inoculations with both Yersin and Haffkine, that while they were very sick all recovered. He also cites a case of plague developing in a child twenty days after inoculation with Haffkine alone—recovered.

The immunity conferred by an inoculation of Haffkine generally last six months or longer.

It has probably been noticed that in considering the methods to be instituted for control of the disease in an infected town quarantine has not been mentioned. This will prove useless except in spe-

cial instances, as no cordon placed around a town or district of any size will prevent people passing through, and certainly will not deter the panic-stricken rats that migrate from their deadly haunts.

Contacts either with human cases or from living in houses in which plague-stricken rats have died should be kept under observation for seven days. Whether they should be isolated and detained in quarantine would depend upon the extent of infection in the town.

In conclusion I will summarize as follows:

1. In towns threatened with plague sanitary measures should be instituted to place them in as good a condition as possible from a rat standpoint. The effective way to repel an invasion is to be prepared to meet it.

2. A careful watch should be maintained in order to detect unusual mortality among rats, and upon the appearance of the disease in these animals the most energetic measures should be instituted to eradicate the infection.

3. Rat plague should receive the same consideration as if the cases were in man.

4. Plague is generally introduced in healthy localities (1) by rats and their fleas, and (2) by infected cargo or food, man and his effects being of secondary importance.

5. Plague is transmitted from rat to rat by fleas, and these insects are also responsible for the transmission of plague to man in the majority of instances.

6. The most effective measures for the control of the disease in infected centers are rat destruction, evacuation, and inoculation.

A SIMPLIFICATION OF THE JAKOBY-SOLMS RICIN METHOD FOR PEPSIN DETERMINATION.

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF INTERNAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

The ricin test for the determination of pepsin, according to Jakoby and Solms,[1] is made as follows: 1.0 gram of ricin is dissolved in 100 c.c of a 5 per cent. sodium chloride solution, and filtered. Two c.c. of this filtrate is mixed with 0.5 c.c. decinormal HCl solution. One c.c. of the diluted stomach contents is added and allowed to remain at blood temperature for three hours. Ferments clear up the ricin deposit. The quantity of pepsin is determined from the amount of dilution in which the stomach contents will cause a disappearance of the ricin deposit.

Solms designates that amount of gastric juice which is just sufficient to clear up entirely the 2 c.c. of 1 per cent. ricin solution in three hours when kept at blood temperature, as one pepsin unit. Normally, stomach contents contain about 100 pepsin units to the cubic centimeter. Witte[2] and others made control tests and recommended the method as practical.

Lately two more pepsin tests have been described. Fuld's[3] method consists in employing a solution of edestin instead of ricin. Edestin, however, is at present difficult to obtain and could therefore hardly be recommended in practice.

The other test is by Gross[4] and consists in mixing a 1 per mil solution of casein, containing 16 c.c. of 25 per cent. HCl to the liter with the filtrate or its dilutions and leaving it for one-quarter hour in the thermostat. Then a few drops of a concentrated solution of sodium acetate are added, resulting in a precipitate if the casein has not been digested. If it is digested the solution remains clear. The test is sensitive and practical, but it suffers from the disadvantage that we have to deal frequently with minute precipitates in contradistinction to the ricin test, where there is a strong precipitate the disappearance of which can readily be recognized.

Of all methods for the approximate quantitative determination of pepsin the ricin test is the most practical. For general use, however, Jakoby and Solms' method is still a little too complicated. I have, therefore, attempted to simplify the same. First, I have had constructed a suitable apparatus for the test; secondly, I have reduced the time from three hours to one-half hour.

The apparatus (see figure) consists of a cylindrical glass, surrounded by a vacuum. This glass tube contains a frame holding twelve graduated pepsin tubes. The whole apparatus can be filled with water and corked. Each pepsin tube is marked with a different letter and shows a mark at 2 c.c., 3 c.c., and 3.5 c.c. The lower part is, furthermore, graduated into millimeters. Thus we may dispense with pipettes and measuring glasses.

C
Apparatus Made By Eimer & Amend New York
For Dr Max Einhorn April 1908

Proceed as follows: Fill each pepsin tube up to 2 c.c. with 1 per cent. ricin solution, then add up to the 3 c.c. mark filtered and diluted stomach contents, and finally add decinormal HCl solution up to 3.5 c.c. The tube is well corked, shaken up thoroughly, and then placed into the frame. The letters on the tubes identify the various dilutions. The vacuum tube is filled with fairly hot water (50° to 60° C.), the frame with the pepsin tubes is placed in it, then the apparatus is corked and allowed to stand for half an hour. Observations are taken of the time at which the deposits in the various tubes disappear and are noted. After thirty minutes the

amount of precipitate left in any of the tubes is recorded.

The advantage of the modification lies in the fact that the test is simpler, that a thermostat is not needed, and that it consumes less time. From numerous observations taken together with Dr. George L. Laporte, and which will shortly be published by us, it appears that this modification of the ricin test is to be recommended.

In making the test, the dilutions of 10, 20, 40, and 100 are most serviceable. Normally, the precipitate disappears in a dilution of 10 or 20. If a precipitate is present at 10 the pepsin is diminished, if it disappears at 40 the pepsin is increased. In achylia or marked subacidity the filtrate is used undiluted or only slightly diluted (2 to 5 times).

I have often tried to determine whether there is a definite constant relation between the rapidity of disappearance of the precipitate or the amount of precipitate left after a certain time, on the one hand, and the amount of pepsin present, on the other hand. We may say that the larger the quantity of pepsin, the more rapidly the deposit will disappear, and the smaller it will be after a certain part of the time necessary to make it disappear entirely. This is plainly to be seen in the following tests, which may serve as examples from a larger number of similar tests:

TABLE OF THE BEHAVIOR OF THE RICIN TEST FOR PEPSIN DETERMINATIONS IN GASTRIC FILTRATES, WITH A STATEMENT OF TIME AND DILUTIONS.

Name	Meal	Time of Removal	HCl	Acid	Dilution	Ricin Deposit Disappeared in	Amount of Deposit After ½ Hour
		Hrs.				*Min.*	*Cc.*
1. Zingari.....	Milk and eggs.	1½	0	110	0	3	
					10	7	
					40	20	
					100	30	0.2
2. Schinper.....	Test Breakfast	1	40	60	10	25	
					20	30	0.1
					50	30	0.3
3. Goldman.....	Test Breakfast.	1	20	60	10	10	
						22	
						30	0.1
4. Carroll.....	Test Breakfast.	1	50	70	10	15	
					40	30	0.2
					100	30	0.3
5. Miss Murphy....	Test Breakfast.	1	+	60	5	27	
					10	30	0.3
					40	30	0.5

It cannot, however, be said that there is a constant relation between the amount of pepsin and the rapidity of the disappearance of the precipitate or the quantity of the remaining deposit. In No. 1 the deposit disappears in the undiluted contents in three minutes; a dilution of 10 ought to have made it disappear in thirty minutes; in reality, it was clear in seven minutes; in No. 4 the remaining precipitate, after thirty minutes, is 0.2 c.c. when diluted 40 times, and 0.3 c.c. when diluted 100 times, whereas, if it were in direct proportion, there should have remained 0.5 c.c. precipitate in the dilution of 100.

In pepsin determinations for clinical purposes, however, we do not have to deal with exact quantitative amounts, but only with approximate determinations. This can be obtained for practical purposes with sufficient accuracy by the ricin test just described.

TUBERCULOSIS OTHER THAN PULMONARY TREATED WITH TUBERCULIN.—REPORT OF CASES.*

By G. R. POGUE, M.D.,

GREELEY, COLORADO.

Owing to the many persons suffering from pulmonary tuberculosis who come to our State seeking health, many of us have given our attention to that form of the disease, and have often overlooked tuberculosis of other organs that may coexist with the pulmonary lesions. I mention this, as most of the cases herein referred to had more or less lung involvement, and consulted me for pulmonary tuberculosis. Only those who had the disease in a moderately mild form were subjected to the specific treatment. It had been early recognized that cases with extensive pulmonary lesions were poor subjects for specific treatment even when no other organs were involved.

When there was any doubt as to the diagnosis, the tuberculin test was used. Only such cases as gave a positive reaction were put on treatment. Koch's old tuberculin in doses of 0.1 to 5 mg. was used for diagnostic purposes.

It is only by the lapse of years that we can be at all positive as to the results in any case of tuberculosis, where there has been an arrest or apparent cure of the disease. This report covers a period of six years, the last patient being off treatment for more than twelve months. While sufficient time may not have elapsed in some of the recent cases, the immediate results were very satisfactory, and, drawing conclusions from past experience with similar cases, it was considered proper to class them as arrested.

It is not my purpose to attempt to discuss the pathology of these different lesions, as tuberculosis is practically the same, no matter what organ or tissue may be involved. The only difference being in the extent of the lesion and the stage of the disease, whether closed or open.

In the past, tuberculosis of other organs than the respiratory has been considered as belonging to the domain of surgery, and probably in no disease has surgical interference so often failed to accomplish the desired end as in tuberculous adenitis. When we consider the impossibility of reaching and removing all the infected glands, the great risk of infecting the field of operation by liberating bacilli from some easily ruptured gland, and the probable chance of a recurrence or spread of the disease to some other organ—often the lungs—we should certainly be ready and willing to investigate any other mode of treatment that promised equally as good or even better results. This is my only excuse for presenting this subject at the present time. Tuberculosis of other tissues and organs that is so often considered surgical comes under the same heading.

In tuberculous adenitis treated specifically, we not only saw healing of discharging sinuses, but the glands were reduced in size, leaving only small hard nodules, which were neither visible nor painful, and

*Read at the first annual meeting of the Boulder County (Colo.) Medical Society, April 2, 1908.

in no case has there been a spread of the disease or a recurrence.

In any form of tuberculosis an early diagnosis is of the greatest importance, if we are to expect the most satisfactory results. Many times we have great difficulty in persuading our patients to accept our diagnosis. This often leads us into waiting too long, with the loss of much valuable time, for structural changes will then have become too great and it is impossible to restore the organ to its normal condition or nearly so. This is especially true in joint tuberculosis, and the best we can look for is an arrest of the process. A stiff joint with a fairly useful limb may be considered a very satisfactory result in many cases.

The same general line of treatment as to diet, rest, and fresh air was carried out in these cases as in pulmonary tuberculosis. In joint tuberculosis, Bier's hyperemia was employed in conjunction with tuberculin. Here also mild "joint exercise" was employed, following the use of the restricting bandage.

The following cases are reported at some length, each being typical of the class they represent. There were ten cases of infection of the cervical glands, all complicating pulmonary tuberculosis. Of these, I shall refer to only two:

Case No. 60.—Male, æt. 25, wt. 143 lbs. Seen first September 20, 1902. Mother died of tuberculosis in 1888. Has had enlarged cervical glands for three years. During the last ten months they became quite large and tender. Operation had been advised several times, but refused. Came to Colorado four months ago. Has gained three pounds. Chest examination showed slight infiltration of right apex. There was morning cough, no tubercle bacilli in the sputum, temperature 36.8° C. Severe reaction to 0.5 mg. Koch's old tuberculin. Temperature, 38.4° C. Under small interspaced doses of tuberculin, glands were gradually reduced in size, and at the end of six months had practically disappeared. September, 1905, no reaction to 2 mg. T. O.

Case No. 146.—Male, æt. 34, wt. 135 lbs. Seen first March, 1904. Has lived in Colorado most of his life, especially for the last twenty years. First noticed enlargement of cervical glands in 1897, since which time they have gradually been growing worse, had drainage operation done in 1901. Have been discharging more or less since. Examination revealed a large open wound above the clavicle on left side. Smaller wounds on right. Apex of left lung involved. Numerous tubercle bacilli and streptococci in sputum, streptococci in discharge from wound, temperature 38° to 39° C., chills and night sweats. Under antistreptococcus serum the associated infection was soon cleared up, temperature became normal, chills and night sweats ceased. He was then placed on specific treatment, and at the end of three months had gained twenty-three pounds, wounds were all healed, cough and expectoration had ceased. Was kept on treatment for three months longer. Disease arrested and no signs of recurrence up to the present time.

There were four cases of tuberculous otitis media. One has not been heard of for two years. The history of the other three is up to date. All are off treatment four years, with no return of the disease. Hearing was restored only in one case to anything near normal. I shall here refer to only one case.

Case No. 9.—Male, æt. 38, wt. 150 lbs. Seen first January, 1900. Had cough, slight expectoration, purulent discharge from right ear, which had existed for some months. The patient refused to accept the diagnosis of tuberculosis at the time. Not seen again until August 10, 1901, when he had a severe pulmonary hemorrhage, following which tubercle bacilli were found in the sputum. Ear had been discharging pus in the interval between January, 1900, and the time of his hemorrhage. September 20, 1901, was put on tuberculin. At the end of three months all discharge from ear had ceased, cough and expectoration greatly reduced. Four months later cough and expectoration had ceased, since which time there has been no return of any signs of the disease. At present his hearing in the right ear is fairly good. Weight, 184 pounds. For the past five years he has done work on his farm, and appears to be in perfect health.

There were three cases of tubercle deposit in the pharynx, but in only one was there ulceration or open tuberculosis. The interesting point about these cases was the opportunity to study the local reaction from the administration of tuberculin in small doses, on visible tubercles. Six to eight hours or more after an injection of tuberculin there was always to be seen a congested zone around the tubercles, and in the ulcerating case around the tuberculous area.

Four cases of tuberculosis of the bladder were under tuberculin treatment. In these cases the microscopic findings were apparently positive. The possibility of mistaking the smegma bacillus for tubercle bacillus was recognized. In the absence of animal experiments for the purpose of differentiation, the patient was given the benefit of the doubt, and the results seem to bear out the diagnosis. Tuberculosis of the bladder is practically always secondary, and generally the result of tuberculosis of some other part of the genital or urinary tract, and treatment directed to the bladder can have but a temporary effect, as it does not reach the real seat of the disease. It was for this reason that tuberculin was depended on in these cases. From the statements of others and my own limited experience in this field, I should recommend a trial of the specific treatment in bladder tuberculosis before attempting surgical interference.

Three cases of joint tuberculosis were treated by Bier's method of hyperemia plus tuberculin. The more rapid results of the combined method would point to the value and necessity of stimulating the tuberculoopsonins when passive hyperemia is employed in the treatment of such cases. I shall refer to only one case of this class:

Case 198.—Male, æt. 29, wt. 138 lbs. Seen first January 10, 1906. Gave history of having lung involvement for about three years. Had been in Colorado two years. Examination showed involvement of upper lobe of right lung, tubercle bacilli in sputum, swelling of right wrist with characteristic flexed position of hand. Owing to the absence of favorable results following the treatment of such cases with tuberculin by others, I decided to try the combined treatment of passive hyperemia and tuberculin in this case. He was given Koch's new tuberculin in doses of 0.0002 to 0.001 mg. every ten days. The restricting bandage was applied from one to two hours twice a day. The first two months' progress, in so far as the joint lesion was concerned, was almost nil, except that the pain was less on attempted motion. At the end of four months, pain and swelling had almost disappeared. At this time the T. R. was discontinued and the patient instructed to keep up the use of the bandage. September, 1906, four months after T. R. had been stopped, he had no cough or expectoration and the joint disease seemed to have been arrested, but joint somewhat stiff. I probably made a mistake here in not giving

more "joint exercise," as recommended by Bier and his followers. Seen last, March, 1907, when he had good use of hand and somewhat better motion in joint.

The other case of tuberculosis of wrist, quit treatment at the end of three months, with some improvement. In a case of open tuberculosis of index finger of left hand, the result was all that could be looked for except a rather stiff joint, a condition that existed when put on treatment.

Tuberculosis of the testicle occurred in two cases. The second one, being the most extensive, is reported in detail:

Case 150.—Male, æt. 26, wt. 134 lbs. Seen first May 28, 1904. Father and one brother died of tuberculosis some years ago. About April 1, 1902, had orchitis (right testicle), which was pronounced tuberculous, and was removed October, 1902. In the spring of 1903, he began to cough, had fever and night sweats. Came to Colorado October, 1903. Had lost ten pounds during the past three months. Examination showed involvement of the upper lobe of the right lung and apex of the left. Left testicle swollen and tender. Temperature 37.7° C., pulse 108. T. B. in sputum numerous. Was on small doses of tuberculin for five months. An abscess formed in testicle, which was drained, and the wound healed in about three weeks. November, 1904, cough much less. No T. B. in sputum, able to do light work, weight 149 pounds. At present no cough, health good, and weight over 180 pounds.

Case 21.—Did not require any operative procedure, and responded more rapidly to treatment. February, 1906, was in good health (about four years after treatment had been discontinued).

When tuberculin was first introduced by Koch, its properties and action were practically unknown. Each man who used it seemed to have his own ideas as to dosage and physiological action. Even to-day we know but little about its physiological action, but there seems to be a more rational idea as to dosage. The work of Wright has given us an explanation of the action of tuberculin, which seems very feasible, especially under certain conditions, *viz.*, when the tubercle bacilli are free in the tissues and can come in contact with the body juices and the phagocyting leucocytes, as in open tuberculosis. In closed tuberculosis, conditions are different.

A diagnosis of tuberculosis can never be made until after tubercle formation has taken place. Not only has tubercle formation taken place, but very probably many generations of tubercles have formed and ruptured before the lesions have become large enough to produce symptoms from which we could make a diagnosis.

Granting that Wright's theory is correct in so far as it goes, we still have in every case the unruptured tubercle to contend with. "If the walling-in process be sufficient, the imprisoned bacilli disintegrate and die under the process of caseation, liquefaction, and absorption, or calcification, and there is no further harm to the economy, but if the encapsulation be insufficient, the bacilli migrate radially and set up new foci of the disease." (Cornet.)

The capsule of the tubercle is a nonvascular fibrous structure, which serves two purposes: It protects the tissues against the growing and multiplying bacilli; it also protects those same bacilli from the bactericidal substances that may be present in the tissues, whether those substances be the product of natural or artificial immunity. Recently we have heard much about producing immunity by the use of certain tubercle bacilli products introduced into the system, but investigation shows that any immune bodies thus produced have no action upon the encapsulated bacilli. We cannot get around the fact that Nature's way of arresting and curing tuberculosis is the only method by which we may hope to win, viz., by encapsulation, and this encapsulation must be complete.

In visible tuberculosis, as of the eye, pharynx, larynx, or mucous membrane, it has long been noticed that some hours after an injection of any of the tubercle bacilli products, in small doses, a congestion is always produced around the tubercles. Such hyperemia aids in the production of new tissue to the capsule, where Nature has already made an attempt to protect the host. This is what might be considered as the second physiological action of tuberculin.

In the stimulation of the production of tuberculo-opsonins, Wright has shown the necessity for the small dose. The same small dose produces the hyperemia around the tubercle. Seven years' experience with tuberculin, used in small doses, has convinced one of its value in properly selected cases. At no time have I found it necessary to increase the dose to anything like that advocated by some writers.

Tubercle bacilli preparations seem to have a double action when introduced into the circulation of a tuberculous individual, especially in the early stages of the disease: (1) The stimulation of the production of tuberculo-opsonins, which opsonins have a certain unknown action on tubercle bacilli that are free in the tissues, so preparing them that they are readily taken up and presumably destroyed by the phogocyting leucocytes. (2) The causing of a hyperemia around the tuberculous area, thus aiding the process of encapsulation. In both cases the small dose is called for.

We have only begun to learn, in a small way, the value of tubercle bacilli products in the treatment of tuberculous lesions. As the physiological and therapeutic action of the drug becomes better understood, its application in suitable cases will become more general. Tuberculin can never be considered a specific in tuberculosis, but at the present time we know it as a most valuable adjuvant to other well-recognized therapeutic agents in the treatment of tuberculous lesions in the early stages of the disease.

EARLY DIAGNOSIS OF CARCINOMA OF THE SIGMOID.*

By EDWARD MILTON FOOTE, M.D.,

NEW YORK.

VISITING SURGEON TO THE NEW YORK CITY HOSPITAL.

Carcinoma of the sigmoid forms less than two per cent. of all cancer.[1] Its relative importance in abdominal diagnosis is, however, somewhat greater than these figures would indicate, as it holds third place in order of frequency of gastrointestinal cancer, the stomach coming first, and the rectum second. It has an especial interest for the surgeon, since it grows slowly, and does not form distant metastases for a long time. It is also accessible, and is situated in a part which can be sacrificed almost with impunity. But to enter this attractive surgical field under favorable circumstances, an early diagnosis is necessary; and the difficulties which surround an early diagnosis of carcinoma of the sigmoid are a challenge to physician and surgeon alike.

The anatomy of this region is simple. The sig-

*A paper read at the annual meeting of the Monroe County Medical Society, held at Rochester, N. Y., May 19, 1908.

moid forms a loop about 18 inches long, with a short mesosigmoid above and below, and a longer one in the middle of the sigmoid. Its arteries are branches of the inferior mesenteric; its lymphatics drain into the lumbar glands. Its own lymphatic glands are less numerous than those of other parts of the intestine. It follows from these facts that a removal of a part of the sigmoid, and the corresponding part of its mesentery, is not a difficult operation, but that such an operation will be a complete removal of the carcinoma only in the early stages of the disease. When the carcinoma has spread to the lumbar glands, its complete removal will be impossible.

Before taking up the symptoms upon which we must rely to make an early diagnosis of carcinoma of the sigmoid, let me give very briefly the histories of three patients upon whom I have operated at different times for this disease.

Case I.—The first was a man aged 53, who for six months had suffered from increasing constipation, with a good deal of pain in the lower left abdominal quadrant. The pain and constipation had at times been much worse than at others, so that on several occasions the patient had been threatened with complete obstruction if one may so express it. He had not observed any blood or mucus in the stools. There had been a gradual but progressive loss of flesh and strength, but up to the occurrence of an acute obstruction for which I was consulted, he was able to attend to business every day. When I first saw him there had been no movement of the bowels for four or five days, and there was gradually increasing vomiting, abdominal distention, and pain. He was still in good general condition. In other words, he had the symptoms of a complete obstruction of the large intestine low down, for the relief of which immediate operation was indicated. I held the hope and expressed it to the family that the cause of obstruction might be purely mechanical, such as a volvulus. In the light of subsequent experience I know such a hope to be absolutely groundless, for the man's history, though less exact in details than we should like it to be, is typical of carcinoma of the sigmoid. Operation revealed that the obstruction was due to such a growth; that the disease had involved the whole wall of the intestine, and had also attached to it two loops of small intestine. An artificial anus enabled the patient to go about in comparative comfort for some months, and postponed the death for more than one year.

Case II.—The second patient was a woman nearly fifty years of age, who was slowly dying from recurrent carcinoma of the breast. She had the same abdominal symptoms as the man just spoken of. There was gradually increasing constipation with occasional acute attacks, going on to almost complete obstruction. As a tumor was palpable there was no difficulty in establishing the diagnosis. She would not consent to operation, however, until complete obstruction occurred. By that time the growth in the sigmoid had already become attached to the bladder, so that complete removal was out of the question, even if she had not had a recurrent carcinoma of the breast. An artificial anus was established which performed its functions well until death, about six months later.

These palliative operations are a physical relief to the patient but they bring little credit to the surgeon, since the attention of the patient and his family is fixed, not on the pain which he has escaped, but on the sad fate which is before him.

Case III.—The third patient presented a more pleasant surgical task. Mrs. L., aged 55, a stout Irish widow, not unfamiliar with beer and whiskey, had always been healthy. For some months previous in her admission to the New York City Hospital she had suffered with constipation, rarely having more than two movements a week, and often only one. The stools were small and hard, otherwise normal as far as she had noticed. Associated with the constipation there was a feeling of itching or burning in the lower left side of the abdomen. One night she awoke with cramps in the abdomen. There had been no movement for two days. This was not unusual, but she did not like the severe cramps, and she took the following day, in order to relieve herself, citrate of magnesia, Seidlitz powders, and salts. They produced vomiting, but no movement of the bowels. The vomiting was a new symptom. In one of the medical wards of the hospital, enemeta and additional cathartics failed to effect a passage, and the question of surgical interference was raised.

When I saw the patient she was still in good condition, with no fever and a good pulse. It was then five days since the last movement of the bowels. The abdomen was uniformly distended to a moderate degree and tympanitic. There was no localized pain, nor tenderness, nor muscular rigidity, and no tumor was palpable. It was evident that the patient was suffering from complete obstruction, very low down in the large intestine. Rectal examination revealed nothing abnormal, but the fact that the patient could hold only a pint of fluid given by rectum, confirmed the theory that the obstruction was low down. Peristaltic motion was still active, as shown by rythmic cramps, as well as by auscultation; but no gas passed the anus. The diagnosis made was stricture of the sigmoid, probably malignant, and operation was performed at once.

An incision was made at the outer border of the left rectus. The moderately distended small intestines filled the field of view. The upper part of the sigmoid was brought into the wound, and was not greatly distended. By following it downward, the finger came upon a hard mass, of scarcely larger caliber than the normal intestine, and not adherent to any surrounding part. It was so low down, however, that it could be brought out of the wound only by dividing a part of its mesocolon. It was a constricting tumor of the sigmoid, and it had already penetrated the serous coat, where it was growing in little red masses characteristic of a carcinoma.

The affected intestine and a considerable portion of healthy intestine both above and below the tumor was freed by division of its mesentery, and brought well out of the wound. The peritoneal cavity was closed around it, and the loop of bowel wrapped in gauze. Owing to the necessary division of blood-vessels, nearly the whole of this displaced bowel became gangrenous. This had no effect on the subsequent steps of the operation, but spoiled the pathological specimen.

A week later the surplus bowel was excised and the ends sutured. Owing to the rigidity of the intestinal wall, it was difficult to approximate the two ends properly, and the suture did not hold. Another plan was then adopted to reestablish the continuity of the gut. The intervening septum, or spur, was cut through by crushing it between the jaws of a large curved clamp. This was done three times, at intervals of a few days, until a deep division of the septum was obtained. Only at the third application of the clamp did the patient feel any pain. The opening in the bowel was then closed once more by suture, and this time the stitches held. A small fistula still remained, which healed spontaneously, as there was an ample lumen at the point of resection and suture. This course of operative treatment

occupied about three months, or nearly six months, if one reckons the time until the fistula was finally healed. Twenty months later the patient was in excellent health and apparently free from recurrence.

Analysis of Early Symptoms.—Carcinoma of the sigmoid occurs in both men and women. The age of the patient is usually between forty and sixty years. Early symptoms naturally fall into three groups. There are the local symptoms of pain, tumor, and abdominal distention; the general symptoms of altered stools, loss of flesh and strength, and cachexia; and a third group of symptoms due to the presence of partial or complete obstruction of the bowel.

Of the local symptoms, pain is the most important and usually the first noted. It is referred to the lower left quadrant of the abdomen. It varies greatly in amount in different cases. It may be slight or severe. If present at all, it is more or less steady until the tumor begins to interfere with the passage of the feces through the sigmoid. Then the pain comes on in rather distinct waves, as the colon by increased peristalsis tries to force its contents through the narrowed sigmoid. Both kinds of pain, the steady kind and the peristaltic kind, are much more marked at times when the fecal masses are hard and accumulate in unusual amount.

The presence of a tumor is not usually observed at an early stage of the disease. Indeed, when it occurs early, it is rather suggestive of nonmalignant disease, as is mentioned in a later paragraph on differential diagnosis.

Abdominal distention in an early stage of the disease is associated with partial obstruction of the bowel. Otherwise it is not of common occurrence, and has little diagnostic value, being found in too many other conditions.

Increasing constipation is an almost constant symptom. Taken with the pain, it forms the most reliable basis for early diagnosis. But the constipation does not increase steadily. On the contrary, there is usually an irregularity in the increase, so that one may well speak of acute attacks of constipation, superimposed upon a chronic constipation. That is to say, the movement of the bowels will become scanty and infrequent, and perhaps cease for three or four days. Then, as the result of cathartics or enemata, there will be three or four movements, the last probably loose. After this the bowels will act satisfactorily for a few days, or possibly for some weeks. Then another attack of constipation comes on. Inquiry will show that these attacks of constipation tend to recur at shorter intervals and that stronger cathartics are required to overcome them.

Alternating constipation and diarrhea are a natural development of this increasing obstruction, but are usually not well marked until an ulcer forms at the site of the tumor or in the damaged intestinal wall above it. Such spontaneous diarrhea following a period of constipation is not to be confused with the loose movements following the administration of strong cathartics to overcome the constipation. Such movements cannot properly be classed as a symptom of the disease, and care should be taken to exclude them before making the statement that alternating constipation and diarrhea exist.

The characters of the stools themselves are seldom of assistance in making an early diagnosis. Blood and mucus are rarely seen at an early stage. It is important to remember this, as blood in the stools is usually mentioned as one of the symptoms of carcinoma of the sigmoid. It is a symptom of the ulceration, and, therefore, a later symptom. We are considering here the early diagnosis. One should never decide that a patient has not a carcinoma of the sigmoid because the stools do not contain blood. Many patients who have such cancer go on to complete obstruction or even death, without visible blood in the stools. The occurrence of blood and mucus in the stools is closely associated in time and origin with the alternating diarrhea and constipation.

Loss of weight is an early symptom, though, like cachexia, it is more noticeable at a later stage of the disease. Those who make a practice of weighing regularly all of their patients know that loss of weight is an early symptom of many obscure diseases.

It seems rather odd to class obstruction as an early symptom, but we are justified in doing so both pathologically and clinically. Carcinoma of the sigmoid is usually annular, and often it gives symptoms of partial or even complete obstruction before it has involved more than an inch or two of bowel. This was so in the third case mentioned at the beginning of this paper. Clinically, it must stand at present as an early symptom, for many of these patients do not consult us until they suffer from some form of obstruction. Yet many of them do come earlier for pain, or constipation, or malaise, and we fail to realize the possibilities that underlie these symptoms.

If obstruction occurs, it is of the mildest type possible. For a time some gas may pass the constriction and serve to postpone the marked abdominal distention, which is a feature of all complete obstruction of the large intestine. If the stricture is situated as low down as the sigmoid, complete obstruction may exist for several days before there is vomiting or serious pain or distress. This is, of course, due to the fact that the patient has nearly the whole of his large intestine as a temporary reservoir for gas and feces, so that if he eats little it may be some days before the small intestine and stomach show signs of the obstructed flow.

Physical Examination.—The conditions found upon examination are quite different when an acute obstruction is present and when it is absent. If the patient is seen between the attacks of acute constipation, when the large intestine is not overfilled, examination of the abdomen will reveal tenderness in the left iliac fossa, especially when rectal and abdominal examination are combined. If the patient is thin and a growth is situated in that portion of the sigmoid which is normally palpable, a tumor should be felt at a very early stage of its development. If the patient is stout, or if the growth is situated in the lower part of the sigmoid, a tumor cannot be felt at an early stage. The tumor, if felt, will be small and movable at an early stage of the disease. When the growth has reached the serous coat of the bowel, adhesions form which limit its mobility. A large or immovable tumor palpable within a few weeks after the first symptoms are noticed by the patient is probably nonmalignant; a point which will be again referred to in connection with differential diagnosis.

The rectum is to be examined with the finger and through a tube. If the tumor can be felt, it is of the rectum and not of the sigmoid. Inspection through the endoscope may reveal merely a constriction, or a tumor, or an ulceration secondary to the cancer, or nothing abnormal. Failure to find even a constriction does not prove its absence, since only a little more than the lower half of the sigmoid can be seen under the most favorable circumstances. The tube used for this inspection should be not less than

twelve inches long, though in many cases not more than eight or ten inches can be passed. A simple tube and obturator with light reflected from a head mirror will suffice, if one has not at hand the more elaborate style of endoscope with pneumatic and electric attachments.

Another method of examination which should not be omitted is the pumping of air or water into the rectum and observing resulting changes in percussion and auscultation. Sometimes a distinct gurgling marks the site of constriction.

If the patient is seen during an attack of acute obstruction, the abdomen is distended with gas at least sufficiently to defeat palpation. There may be visible peristalsis. There may be an area of dullness in the left lower quadrant, due to accumulation of fecal matter above the constriction. Water or air injected into the rectum will probably not pass the constriction. In this case, not more than a pint of water can be injected, as this is about the capacity of the rectum. The sigmoid, it will be remembered, holds about a quart, and when the carcinoma is high up in the sigmoid, some of this capacity is available, even though obstruction is complete.

Differential Diagnosis.—Chronic Constipation—In making a differential diagnosis, we shall have to consider first of all chronic constipation. This often shows a tendency to increase as a patient passes middle life, and on account of injudicious diet, lack of exercise, or for some other reason, it varies in intensity, and may even be interrupted by short periods of diarrhea. It may also be accompanied by a diminished appetite, poorer color, and a loss of weight. The chief points which distinguish chronic constipation from the irregular intestinal action due to malignant disease, are the long duration of symptoms and the absence of abdominal pain, except such colic as may accompany an attack of diarrhea. In the simple nonmalignant cases of constipation the symptoms will have lasted for years. However, it is well to remember that a carcinoma of the sigmoid may develop in a person who has long been constipated from some other cause.

Sigmoiditis.—The occurrence of an acute or subacute inflammation of the sigmoid was formerly denied by some of the most prominent writers. Whether they have all retracted or not it is not necessary to inquire. For our purpose it is enough to know that many cases have recently been reported, in some of which the diagnosis has been confirmed by operation. Without going into the various classifications of such inflammation which some writers have proposed, we may also admit that the various forms of catarrhal, ulcerative and perforative inflammation may occur in this region. Such an inflammation may vary in intensity, a it may be confined to the mucous membrane or penetrate the deeper layers of the intestine, or, extending through the intestinal wall, the inflammation may lead to the development of localized abscesses, sinuses, and fistulæ. It is evident that the symptoms in different cases will vary a good deal; and yet it is possible to speak of the typical set of symptoms. The inflammation is usually chronic with acute exacerbations. In the acute stage there is fever with tenderness and muscular rigidity, colicky pain, and perhaps fetid or purulent stools. In the subacute or chronic stage, the patient may be constipated or there may be diarrhea with blood and mucus in the stools. There is more or less constant pain. The sigmoid is palpably thickened and tender for a distance of several inches. Such a tumor is often movable. It does not disappear promptly after an evacuation of the bowels is obtained. The colon above the sigmoid is often distended. A marked restlessness or nervousness has been observed in some patients. Naturally, in these cases there is often a considerable loss of weight, which may be quickly recovered, upon suitable diet. If under treatment the inflammatory symptoms subside, the patient gains in weight, and the stools become normal, the suspicion of malignancy is lifted. If an ulcer of the sigmoid leads to perforation, usually through one of the diverticula, and the abscess which results is limited either by adhesions or because it forms retroperitoneally, the patient will present some symptoms similar to those of malignant disease, but the picture is so essentially inflammatory that a careful investigator is not likely to be misled.

Tuberculosis and Syphilis.—Tuberculosis and syphilis of the sigmoid are so rare that a brief mention of them must suffice. The former leads to adhesive inflammation and sinuses; the latter has its own history in many cases, and generally other lesions in other parts of the body.

To sum up the chief points in differential diagnosis, we may say: If the disease is located in the left iliac fossa, with symptoms of increasing constipation for six months or less, possibly with occasional diarrhea without blood, with local pain and some impairment of strength, there is strong suspicion of malignancy, especially in a person of middle age or beyond. If a small movable tumor can be felt the diagnosis is almost certain.

If there is a history of diarrhea and constipation, with mucus and blood almost from the beginning of the illness, or if the history includes an acute inflammatory attack, or if there is a large movable tumor, or a continuation of symptoms for a year or two without great impairment of health, the affection is probably not malignant.

Complete Obstruction.—If the patient when seen is suffering from complete obstruction, it will be necessary to consider, in addition to the possibilities mentioned above, mechanical obstruction, such as volvulus of the whole sigmoid, obstruction due to bands, etc. The absence of symptoms previous to the occurrence of the acute obstruction, will usually serve to differentiate the two kinds of obstruction; but should a mistake be make in this direction, it is not serious, as the treatment indicated is in both cases immediate operation.

Treatment.—It is not the purpose of this paper to treat the subject of carcinoma of the sigmoid exhaustively, but rather to suggest the possibilities of an earlier diagnosis than is usually made. The remarks upon treatment will, therefore, be very brief.

It has for many years been recognized that primary resection of the large intestine followed by closure of the abdominal wound is a dangerous procedure, even when the intestine contains only the normal amount of fecal matter. There are several reasons for this, which it is not necessary to mention in detail, but the chief one is undoubtedly the absence of peritoneum from a considerable portion of its circumference. The risk of resection is greatly increased if performed in the presence of partial or complete obstruction.

As long ago as 1879, Baum[2] proposed and carried out a plan to lessen the risk. His idea was to perform colostomy some distance above the tumor in order to relieve the distention, if such existed, and also to divert the fecal stream. Some days later he performed a resection, and the sutured intestine had time to unite before any feces passed through it. This plan of procedure has been followed by many surgeons and is still in use to-day. If the tumor is

situated in the sigmoid, the artificial anus is usually established in the transverse colon.

In 1892, Bloch[3] performed what he called an extraabdominal resection of the sigmoid, dividing the operation into three steps or stages. At the first one, the tumor was brought out of the abdominal wound, and the intestine was opened above the constriction. At the second step, taken some days later, the protruding intestine was resected. The operator then waited four months, to make sure that there was no local recurrence of the tumor, and then performed the third part of the operation, which consisted in freeing and suturing the edges of the intestine.

This method of operating seems to possess certain distinct advantages over Baum's method, especially in cases of carcinoma of the sigmoid. The technique was perfected by Mikulicz,[4] and a description of it was published by him in 1902. His plan is to free the tumor and the adjacent involved lymphatics, dividing so much of the mesocolon as is necessary to bring the affected intestine out of the wound. The edges of the parietal peritoneum are stitched to the upper and lower portions of the intestinal loop with catgut in order to close the peritoneal cavity, and to prevent the intestine from drawing back into it. The wound in the skin is also partially sutured. In his earlier operations, Mikulicz delayed resection for one, two, or three days. In his later operations, he cut off the protruding loop of intestine at once, and tied in its upper opening a large tube, in order to convey the feces away from the wound. This immediate resection is undoubtedly the proper procedure to follow, for the loop often becomes gangrenous in part, owing to the disturbance of its blood supply. Two or three weeks later, Mikulicz crushed the septum or spur between the upper and lower openings in the intestine, and closed the external intestinal wound by suture. This reduces the operation two steps, unless it is necessary to repeat the second one.

Performed in the manner last described, resection of the sigmoid flexure is almost without risk; whereas by Baum's method of operating there is some risk of peritonitis, even when an empty intestine is resected and sutured. Baum's method also requires two abdominal wounds.

The chief objection which may be urged against Bloch's extraabdominal resection is the possibility that it may be followed by hernia. If this occurs a third operation will be required in order to cure it, but as the intestine need not be opened at this operation, it does not add greatly to the risk. All things considered, this is a most satisfactory method of operating for carcinoma of the sigmoid, and deserves a much wider recognition than it enjoys at present.

There is one point in connection with crushing the septum which I have not seen mentioned, and which is worth observing. Before the intestine is sutured to the parietal peritoneum, its upper and lower portions should be slightly rotated upon themselves, so that their peritoneal surfaces will lie in contact. If this is done, the septum will contain no sensitive nerve fibers, and may, therefore, be crushed absolutely without pain.

THE PAINFUL CUTANEOUS ZONES IN VISCERAL DISEASE.*

By M. D. BLOOMFIELD, M.D.,
PHILADELPHIA.
MEMBER OF THE NEUROLOGICAL STAFF OF THE JEFFERSON MEDICAL COLLEGE.

It is surprising that such an important subject as the one indicated by the strain of this paper should have received so little attention. In 1893, Henry Head of England published in Vol. XVI. of *Brain* an article in continuation of his Graduation Thesis on the same subject, appearing in 1892, in which he maintained that pain caused by visceral disease is referred to definite cutaneous areas, which are distinct for each organ affected, and in which tenderness often exists. These areas correspond to the distribution of the pathic fibers contained in one or more posterior spinal roots. By mapping out the tender area, it is possible to ascertain from which portion of the spinal cord the affected viscus receives its sensory fibers. He found that the tenderness from visceral disease extends as a band around the body and over points where pressure cannot affect the diseased organ. Pain from affection of the peritoneum and pleura is local, not referred, and the tenderness is absent from bony points, such as the iliac crest and vertebral spines, where pressure does not affect the serous membrane. The reflexes are always exaggerated over the hyperalgesic zone.

Cedrangalo, Scherrington, and Starr have found, after a long experimentation, these hyperesthetic zones described by Head, the areas being segmental regions of the body corresponding to the various viscera.

Bennett, in the *Lancet* of October 12, 1907, reports three cases in which purely thoracic symptoms led to the diagnosis of acute appendicitis. In two of his cases of gangrenous appendicitis, they exhibited thoracic symptoms. He found those areas of hyperesthesia to correspond roughly to the anatomical divisions of the abdominal wall so far as the point of greatest intensity of the hyperesthesia is concerned. He found the hyperesthesia most intense (*a*) at McBurney's point, (*b*) at the umbilicus, (*c*) at the level of the ninth rib. On the right side the hyperesthetic area over McBurney's point is usually associated with the appendical diseases. The zone corresponding to the umbilicus is frequently associated with inflammation or abscess above the lower surface of the diaphragm. The pleura or peritoneum must always be affected to elicit this phenomenon. In the absence of involvment of these coverings, disease of the viscera cannot very well be interpreted by this sensory phenomenon. However, I have been able to elicit it in gastric ulcer and in aneurysm of the ascending arch of the aorta, where the serous coverings could hardly have been affected.

In chronic disease, with resulting pathological formation of new tissue causing adhesions, it is hard to elicit the zones. However, in many cases of chronic vesceral involvement, I have been able to elicit them. In the acute stages of visceral involvement they are conspicuously observed. Bennett has found that when the hyperesthesia is marked in a disease of acute onset, it most frequently points to surgical complications, usually to abscess, empyema, or gangrene.

Joseph Fränkel of New York, in a paper read before the Neurological Society, April 19, 1906, says that he found the evidence of disturbed sensation in visceral disease a valuable sign. In his experience

*Read at a meeting of the Philadelphia Neurological Society April 24, 1908.

he found it a great aid at the bedside, frequently illuminating many ill-defined and vague symptoms.

The explanations of the phenomena are necessarily theoretical and the views so numerous that I will only briefly mention those most frequently considered: (1) The epicrutic and protopathic sensory pathways. (2) The existence of special areas of specific sensibility. (3) The intercommunication of, or the direct accompaniment of, an afferent to every efferent nerve. (4) Pacinian bodies. (5) Corticospinal, visceral, and cutaneous zones. (6) Special temperature spots, etc.

The physiological laboratory has taught us that the stomach, liver, heart, lungs, and kidneys can be handled without causing any pain; the pleura, pericardium, peritoneum, meninges, the serous membranes, the skin, the fascia of the muscles, tendon sheaths, periosteal layer, and synovial membranes, on the other hand, give pain when handled. However, recent laboratory research has produced contrary evidence, namely, that the viscera are capable of responding to painful stimuli, though not able to localize them correctly. Dana and MacKenzie, in 1890, were the first to draw attention to the cephalic areas by associating the location of a headache with its possible visceral origin, in bladder, stomach, uterus, etc. Starr and McBurney, in experimentation along this line, conducted at Roosevelt Hospital in New York, elicited this phenomenon in about 12 per cent. of their cases. Wm. H. Thompson has had a variable experience, finding this sign present in a great many cases, and absent in many where it was expected to be most prominent. Hunt has found this a valuable diagnostic aid in cases of gastric ulcer and gallstones, especially in neurotic individuals. I have asked several other prominent clinicians what their experience has been with this sign, but, unfortunately, they had never heard of it.

Method of Eliciting the Head's Lines.—The patient, after having had his history carefully recorded, is given a thorough general examination. When ready to test for Head's lines it is best that the patient lie supine and perfectly relaxed. If possible, he should have no distention of the abdomen, due to fecal accumulation, likewise the bladder should be emptied voluntarily. A pin, toothpick, or any pointed instrument, the fine electrode of the faradic current, test tube of hot or cold water, or even picking the skin up between the fingers, is employed to elicit this reaction. The patient, looking away from the examiner with his mind diverted from himself, the physician places the pointed instrument over the various zones of the abdomen. When the suspected area is reached there is a decided change. Here, the reflex is exaggerated, the pain is more intense, localized. In stroking my pin over the suspected zone, I first lightly touch the skin with the point, holding the instrument in the position as if ready for puncture. If the hyperesthesia is uniformly complained of without the objective reflex, it usually means a psychic element. One will find in such case that the touch with the pin over the same spot a few seconds later causes no pain at all.

A good way to outline a satisfactory area is to test the suspected zone by lines, drawn across the zone, say four inches long, forming by intersections several squares within the square. The center of each little square in the typical case exhibits this hyperesthesia and reflex at the slightest touch.

Occasionally hysteria and other functional and organic nervous affections may stimulate these hyperesthetic areas, but the history of the case, the indefiniteness of the area, the absence of objective reaction in the reflex or hyperemia, the failure to respond in the same way when the area is retested, all speak against the true Head's zones.

In the cases I report below the hyperesthetic zone was a most valuable aid. To me it almost seemed the most important symptom. The laboratory analysis was a complete one, but unfortunately, frequently threw little light as to the real condition.

Case I.—S. B., tailor, age 45, Russian, married, has five healthy children, comes from a healthy parentage. Has always had indigestion. For the last five years has been treated by some of our most eminent specialists for chronic constipation. He always complained of a "hard stool," and pain after eating. The character of the pain was variable. At times it would be at the xiphoid cartilage, sharp, and preceding meals, then dull and constant, frequently boring, aggravated by eating. The location would likewise be varied. During the last year he had lost thirty pounds in weight, felt weaker than usual, pain less, appetite better, but skin more yellowish than before. He had always had a yellowish complexion. Physical examination could detect no evidence of any growth.

Laboratory analysis, according to D. M. Kaplan's chart, which I employ: Blood, October 14, 1907. Hemoglobin, 80 per cent.; R. B. C., 4,850,000; W. B. C., 7,000; basophiles, 1 per cent.; neutrophiles, 74 per cent.; large lymphocytes, 12 per cent.; small lymphocytes, 18 per cent.; larger mononuclears, 3 per cent.; eosinophiles, 4 per cent.; nucleated cells, 5 per cent.; microorganisms, none. The blood examination at the German Hospital, to which I had him admitted, in Dr. Deaver's service, showed similar findings.

Uranalysis.—Twenty-four-hour specimen, 1,500 c.c.; S. G., 1,024; reaction, acid; color, amber; odor, urinous; transparency, fair; sediment, some; albumin, none; urea, 30 grams; indican, plus; chlorides, plus; sulphates, plus; blood, none; bile, none; sugar, none; Diazo, 4 times out of 10 positive; calcium oxalate, present; amorphous urate, present; casts, cylindroids; epithelial cells, none.

Feces.—Number of stools, one; ribbon-shaped, hard, dry, small piece; clay color; little odor; hydrobilirubin, slight trace; occult blood, none; parasites, none; food rests, none; mucus, none; blood, none; a few triple phosphate crystals, vegetable cells, and oil.

Stomach outline, normal; vomitus, none; tube of caliber 34 introduced easily twenty-two inches. Last food taken ten hours previously, consisting of cup of tea, two pieces of toast; time of test, 10 A.M.; quantity obtained, 150 c.c.; gross appearance, particle of bread, apple, crackers, tomatoes.

Chemical Analysis.—Lactic acid, twice out of six tests; free HCl present every time; no butyric or acetic acid; occasional traces of blood, no bile.

Ewald's Test Meal.—Quantity, 200 c.c.; time of ingestion, 9 A.M.; time of removal, 10 A.M.; quantity obtained 300 c.c.; degree of subdivision of particles, almost as ingested, with a very sour odor. Absorption power, poor; iodine appeared 1 hour after administering a capsule of 5 grs. of potassium iodide. These examinations did not point to the real nature of the malady. The only point of interest and bearing seemed to be tenderness on palpating the epigastrium, however with no focal intensity of pain. I tried for Head's zones, and found, at about the eighth interspace, on the right side, an area of hyperesthesia, exaggerated reflex, and delayed hyperemia. There was no nervous element to be considered. In considering the fact that the

patient had been suffering so many years from indigestion, losing thirty pounds within one year, showing evidence of beginning emaciation, despite the negative laboratory examination, and from the light in the nature of Head's zones, I made the diagnosis of beginning cancer of the posterior wall of the stomach. The patient was admitted to the German Hospital, where Dr. Deaver and the house staff, who examined him, did not regard the case as one of cancer, but of chronic constipation. I urged the operation. At operation Dr. Deaver, after a few minutes' search, came across a mass about the size of a large walnut, hard, and situated on the posterior wall of the lesser curvature near the pylorus. Microscopic examination showed it to be a scirrhous carcinoma. A gastroenterostomy was done, and now the patient has gained seventy pounds since the operation, and is enjoying excellent health. Dr. Salinger saw the case with me in consultation.

Case II.—Patient 48 years old, express agent, Hungarian. Mother had cancer of uterus. Is married. Has four healthy children. Always enjoyed good health until last fall, when he consulted Dr. W. W. Babcock for "sour stomach." In about a week's time was much improved, but felt a heaviness after eating, a dull ache lasting for a few minutes, mostly confined to the liver area, and a desire to fall asleep immediately after eating. He again consulted Dr. Babcock, who soon relieved his distress, and the patient was free from all annoyance for two months. Three months after he first began to be troubled with his stomach, he felt himself becoming weaker every day. He could not sleep; he was nervous; his right side felt heavier than before, but he had no particular pain. After eating, he felt "all stopped up." Lost ten pounds in four weeks. Came under my observation February 12, 1908.

Physical Examination.—Showed a splendidly developed, well-nourished man, weighing 185 pounds; he was slightly pale and careworn; tongue coated; reflexes increased all over; no organic affection of the nervous system. Over the liver a tender area was outlined on deep pressure. Stomach outline was slightly increased. There was a well-developed Head zone, area of hyperesthesia, and exaggerated reflex, on the right side of the level of the ninth rib, and in the midclavicular region. After combining the evidence of the laboratory, I diagnosed his condition as probably a malignant tumor of the pylorus, developing from a previous gastric ulcer. The patient, like the previous one, had never vomited during his illness. His bowels were regular, though the passages were incomplete, and the feces were hard and foul-smelling. The patient felt better after eating. I made three analyses of his urine, blood, feces, and gastric contents on three different visits, two days apart, and give below the average findings. After his third visit, I advised him to be operated on immediately. He refused, went to New York, where he received Christian Science treatment for two months. He came back last week to see me.

Physical Examination Three Months after First Visit.—Weight, 138 pounds. Yellowish all over. Palpable tumor about 10 cm. long and 5 high, right below xiphoid cartilage. Could hardly walk, was so weak. Patient is now in hospital, with inoperable tumor of the stomach, impatiently awaiting his call.

Blood.—Hemoglobin, 95 per cent.; R. B. C., 5,000,000; W. B. C., 5,000; basophiles, none; neutrophiles, 68 per cent.; small lymphocytes, 60 per cent.; large lymphocytes, 24 per cent.; large mononuclears, 2 per cent.; eosinophiles, 2 per cent.; transitional, 3 per cent.; microorganisms, none.

Uranalysis.—Twenty-four-hour specimen, 1,800 c.c.; S. G., 1,018; reaction, acid; color, pale; odor, urinous; transparency, clear; albumin, sugar; bile, blood, none; Diazo, negative; urea, 2 per cent.; indican, positive; chlorides, diminished; sulphates and phosphates, increased; calcium oxalate, triple phosphate, and amorphous urates present; a few bladder epithelial cells; no casts.

Feces.—Number of stools in the twenty-four hours, three; countless scybala, in a semisolid, foul, acid-smelling stool; hydrobilirubin, present; no occult blood; no food rest; mucus absent; blood present, most probably from bleeding internal hemorrhoids; a few triple phosphates, calcium soaps, crystals, fat, vegetable hairs, Charcot-Leyden crystals.

Stomach Contents.—Stomach outline dilated. Vomitus, none. Aspirated by tube of caliber 34, introduced 28 inches easily. Last food taken twelve hours previously. Cup of tea, two pieces of toast. Time of test, 10 A.M. Quantity obtained, 300 c.c. Gross appearance, particles of toast in water. Chemical analysis showed no lactic acid; diminished free HCl, no acetic or butyric acids, no bile.

Rieger's Test Meal.—Quantity, 350 c.c. Time of ingestion 11 A.M. Removal, 12:15 P.M. Quantity obtained, 400 c.c. Degree of subdivision of particles but little changed; more acid odor.

In this case, as in the preceding, the painful cutaneous area was one of the most prominent symptoms pointing to a visceral disease.

Case III.—Male, 54, laborer, married, no children. Always enjoyed sound health. Twenty-one years ago contracted syphilis, which soon disappeared after specific treatment, and he felt well until one year ago, when he had a pain in the right shoulder; it was sharp and shooting, and radiated toward the right parietal region. When this pain came on he suffered great agony. At times the pain was worse over the right shoulder and arm. There was a fine tremor of his hands. Reflexes increased. Tongue was coated and tremulous. Pupils dilated, otherwise normal. Vision was unaffected. Inspection of painful area showed nothing. Palpation was most tender over the middle of the right clavicle, and especially so on deep pressure. A mass could be felt which was semisolid, immovable, not expansible. Head's zone was present in the form of hyperesthesia and increased reflex along the right carotid. Pain most intense in the supraclavicular region. Heart sounds were slightly accentuated. Lungs apparently normal. I diagnosed the condition as an aneurysm of the ascending arch of the aorta, and showed this patient to Dr. Gordon, who agreed with me. He was admitted to the Jefferson Hospital under Dr. Kulteyer's care; after treatment, he felt so much improved that he left to go home. Several specialists who had seen the patient, diagnosed his condition as hysteria, brachial neuritis, cervical rib. I had an *x*-ray taken, which showed a tumor of about the size of two fists, passing from the aorta toward the sternum. In this case, after I excluded organic nervous disease and hysteria from the exaggerated reflex and hyperesthesia, I was led to suspect some deep-seated tumor, which was causing these pressure symptoms.

Case IV.—G. A. B., 17, epileptic. Parent, alcoholic. Referred from Gynecological Department for report of an examination, which revealed a highly neurotic state. She was extremely emotional, with no symptoms, however, pointing to direct involvement of the brain, outside of her major epileptic seizures. Stigmata of hysteria, spinal and mammary, were present. No symptom of cardiac dis-

ease. Her chief complaint was a pain along the right iliac region, which was very severe during the menstrual period. I carefully examined her abdomen. The right side gave evidence of hyperesthesia, which, however, would be easily suspected to belong to her hysteria. The left iliac region presented a slight prominence, which was tender to all tests for sensibility. Here there was an actual exaggeration of the reflex, an increased hyperemic area, a more localized and well defined area of greatest intensity to the stroke of the pin. I interpreted her condition as a tumor of the left ovary. On speaking to Dr. Bland after our department reported its findings, he told me it was confirmatory of his examination, which had elicited a large mass of the left ovary.

Case V.—J. W., male, 38, watchmaker, married. Was suddenly seized with pain in the right inguinal region; vomited, and had all the symptoms of shock. Up to this time he had always been a healthy man. On October 18, he recovered from this attack, and came to my office, as the pain, though not severe, still existed. When I examined him I found him normal in all respects, until I came to his abdomen. He had a dilated cecum, a tenderness on superficial, and deep palpation along the course of the right ureter. His urine, however, was normal, except for an increased indicanuria. A hyperesthetic zone, with an exaggerated reflex plus a vasomotor disturbance manifested in the hyperemia exhibited on scratching the skin, and a rectal temperature of 100°, led me to suspect a gangrenous appendix. Dr. Deaver operated on the patient, and took out some remains of the gangrenous organ. For many weeks this patient was in a precarious condition, as he developed a thrombosis of the popliteal artery fou. days after the operation.

Case VI.—Physician, aged 40, seen with Dr. Maurer. Patient was a well-built man, of good musculature, though showing evidence of emaciation. He had always been in good health, except for a susceptibility to neurasthenic attacks, referable chiefly to his heart. His family history was a discouraging one, both parents dying from cancer of the stomach, sister from cancer of the uterus. On December 10, 1907, I first examined his urine, without having seen the patient, reporting back to his physician the presence of albumin, indican, a few red blood cells, and casts in his urine. Ten days later I saw the patient personally, and examined him, finding a large tumor above the gall-bladder. Without going into the details of his present illness, I may briefly state that for the last ten months he had been feeling miserably weak, could not eat, everything nauseated him. Was constipated, and suffered day and night from pain over his liver. I did not subject him to gastric lavage. His condition was too evident. Head's line was most conspicuous over the swollen area. We diagnosed this case as an inoperable tumor of the pyloric end of the stomach. He was seen by Dr. Deaver, Dr. Steinbach, and Dr. Cohen, all of whom advised against operation.

Case VII.—A lad, 18 years of age, who had his right testicle removed two years ago in a hospital in Indiana. He was suddenly seized with severe pain at that time, consulted the surgeon of that town, who removed the right testicle a day after. Dr. Steinbach, who now has charge of the case, at the Jewish Hospital, communicated with the hospital in which he was operated on, and received the report that the testicle was the seat of a beginning sarcoma. Two weeks ago the patient came to see me, suffering from a large mass about the size of a hand in the left iliac region. His mother had died from a tumor. His early history had no bearing on his present condition. To be brief, I may state that he presented the picture of one in the last stages of this malady. A hyperesthetic area was present and an exaggerated reflex was elicited over this mass. I did not subject the patient to a long examination, for he was too weak and sick. Dr. Deaver, who saw him, refused to operate, suggesting as a last resort Coley's fluid. I do not believe the patient went to New York for this treatment. He is now spending the remaining few weeks of his life at the Jewish Hospital.

I recently saw a patient who had been under Dr. Eshner's care for a long time, suffering from a chronic parenchymatous nephritis, who presented a marked hyperesthesia, an exaggerated reflex over both lumbar regions.

The following table gives the result of an examination for the Head lines and zones in 93 cases:

	No. Examined.	*Head's Lines. Present.*
Appendicitis:		
Acute	20	20
Chronic	12	10
Gangrenous	5	2
Uteroovarian disease, with inflammation of the adnexa.	24	10
Gastric ulcer	10	10
Gastric carcinoma	8	7
Ureteral calculus	1	1
Gall-bladder disease	13	7

This is a subject which should receive more attention, not only from our specialty, but from the departments of internal medicine and surgery, and as one requires no other equipment but the patient in which to study and investigate along this line, it should be a welcome field of study for the general practitioner.

In closing, I want to express my deep appreciation to Dr. Dercum and the neurological staff at Jefferson for their kind assistance in my work along these lines.

2012 N. Park Avenue.

FOUR CASES OF PERFORATING ULCERS OF THE ALIMENTARY CANAL.*

By H. BEECKMAN DELATOUR, M.D.,
BROOKLYN, NEW YORK.

In this communication I will present simply the histories of these four cases without extended comment.

Case I.—Male, 33 years, patient of Dr. J. W. Malone, admitted to the Methodist Episcopal Hospital November 13, 1906. Was seized with severe abdominal pain which in thirty-six hours was followed by the presence of a large mass in the epigastrium. Pain still continued, had had chills and considerable temperature. Operation: Median incision above the umbilicus. On separating adhesions below the stomach there was an escape of pus; the peritoneum was not soiled by this, a long strip of zinc oxide gauze was packed into this opening, the peritoneum sutured over this, and the abdomen closed without drainage. The patient was then placed on the right side and an incision made along the twelfth rib of the left side and dissection carried up until the abscess cavity was reached from behind. About three pints of fetid thin pus was evacuated. The end of the piece of gauze introduced from in front was then drawn through this

*Read before the Medical Association of the Greater City of New York, April 20, 1908.

wound and a rubber drainage tube inserted alongside it. Subsequently when the patient took milk by mouth it would immediately appear at the drainage tube, indicating an ulcer of the posterior stomach wall. Drainage was profuse for two weeks but then gradually lessened until the wound healed and the patient was discharged January 31, 1907. In April, 1908, he still continues well and has had no further disturbance from the stomach.

Case II.—T. M. Ireland, male 56 years. Admitted to the Methodist Episcopal Hospital May 11, 1906. Family history negative. He has been generally well and strong. Uses both alcohol and tobacco moderately. Denies syphilis. On May 9 was suddenly seized, during the night, with severe abdominal cramps and vomiting. Before retiring the patient had taken a dose of Hunyadi water and attributed the trouble to that. The onset was very sudden accompanied by collapse and severe pain. His physician gave hypodermically three half-grain doses of morphine at half-hour intervals, with very little relief. During the next day the pains continued, but were somewhat quieted by large doses of morphine and local applications of heat. The pain was referred to the upper abdomen. During the day and next night the patient had several chills. Deep inspiration caused very severe pain in the right hypochondrium. I saw him first forty hours after the onset. Examination at that time was somewhat unsatisfactory owing to the morphine the patient had taken; his mind was clear, the face pinched, he was still suffering severe pain at times, the abdomen was not distended but the muscles of the abdominal wall were contracted. The most marked tenderness was just to the right of and a little above the umbilicus. Pain was more general than at first. The bowels had moved during the day as the result of cathartics. Temperature 101°, pulse 96, respiration 28.

Operation May 11, 9:25 P. M. A five-inch incision was made through the middle of the right rectus muscle, beginning at the free border of the ribs. On opening the peritoneum a slight amount of turbid fluid was evacuated. The gall-bladder was moderately distended. On the inferior aspect of the first portion of the duodenum was seen to be an opening about one-quarter of an inch in diameter with necrosis of some of the adjacent bowel wall. The opening was closed by a continuous silk suture, but there was some difficulty in getting the sutures placed in tissue which would not tear out. The surrounding peritoneum was thoroughly cleaned by sponging. A small iodoform gauze drain was inserted and the wound closed. The patient was returned to bed, showing very little shock. During the succeeding three days there was considerable pain and gaseous distention. No food was given by the mouth. The temperature continued at 101° F. and on the second day some of the wound sutures were removed and some serosanguineous fluid evacuated. On the fifth day the drain was removed and more thin reddish secretion escaped. The temperature then became normal. During the next two weeks the patient was very comfortable and the temperature remained normal. The wound had completely closed. During the fourth week the center of the wound broke down and discharged freely for about ten days, and there was some pain about it. On June 12, an attempt was made to close this sinus. On opening the abdomen, the intestine was found everywhere adherent, and on attempting to break down these adhesions the gut was torn completely across, so friable was the tissue. To repair this a resection of some two inches was done and an end-to-end anastomosis by suture was performed. The abdominal wound was then closed. Reaction from the operation was without shock and in every way satisfactory. From this time there was no further trouble with the wound, but, although out of bed, the patient did not regain his strength, and occasionally would have severe attacks of abdominal pain. The bowels were easily moved. During the night of July 5 the patient was seized with severe abdominal pain in the lower abdomen. This continued during the next day, and the patient rapidly lost ground. I was out of town and did not see him until the afternoon of the 6th. At that time his general condition was such that operative interference was out of the question. He rapidly grew worse, and died on the morning of July 7, thirty-six hours after the beginning of the attack. Postmortem examination showed a volvulus of the sigmoid, with several inches of gangrenous intestine. This was far from the original trouble, and had no direct connection with it.

Case III.—Female, 43 years old, patient of Dr. Joseph Merzbach, was admitted to the Jewish Hospital February 14, 1908. Family history negative, except that her mother, who is 68 years old, has had two attacks of vomiting of blood.

Previous history.—A similar attack to the present confined her for three weeks, six months ago. The present illness dates back about three weeks, and began with pain of a burning character, which started on the right side and traveled to the stomach region and then to the back. This pain would last about one-half to one hour, and then disappear; it came two to three hours after eating. The bowels have moved every day, and stools have been normal—no blood or tarry appearance. During the attacks of pain the patient suffered from gaseous distention. No fever, no cough, no dyspnea, appetite always very good. No urinary symptoms; no headache. Has lost about 20 pounds in the six months.

On the morning of February 14, the day of admission, at about 8 A.M., she had another severe attack of pain in the abdomen. With the attack of pain she vomited a clear fluid, but has not vomited since. The onset of the pain was marked by severe shock and collapse. At the time of admission to the hospital the patient was quite recovered from the shock. Examination at 4 P.M. showed a moderate distention of the abdomen, marked tenderness in the epigastric and right hypochondriac regions, but no tumor could be felt. Temperature was 100° F., pulse 90, respiration 26. Blood examination gave leucocytes 23,600 and polymorphonuclears 93 per cent. A diagnosis of probable intestinal perforation was made by Dr. Merzbach.

Operation 5:30 P.M. the same day. A four-inch incision was made through the right rectus muscle, opening the peritoneum. Gall-bladder appeared in the upper angle of wound and was normal. To the inner side of the incision fresh lymph was seen, so a lateral extension was made to the left partially through the rectus muscle. This exposed the layer of lymph, and a small amount of serum and some adhesions between the colon, omentum, and anterior abdominal wall. The lymph was carefully removed, and on the anterior surface of the transverse colon, about four inches from the hepatic flexure, was found a punched opening one-quarter of an inch in diameter entering the lumen of the gut. The intestinal wall for an inch about this was indurated. This indurated area with the opening at its

center was excised and the opening in the colon closed by silk Lembert sutures. The abdominal wall was completely closed, except for a small strip of iodoform gauze carried to the peritoneum at the center of the incision. Recovery from the anesthetic was prompt and without shock. The future progress of the case was without incident, the patient leaving the hospital on the twelfth day, apparently in the best of health.

Case IV.—J. E., male, 15 years. Admitted to the Jewish Hospital March 24, 1908.

Previous History—Pneumonia a number of years ago. Operated upon for suppurative appedicitis six years ago. From the time of the operation for appendicitis he had been perfectly well until about six weeks ago. Then he began to have abdominal pains, which would come on most often after meals, and would not be referred to any particular part of the abdomen. Two days before admission he was seized with intense abdominal pain which produced collapse. This was accompanied by distressing vomiting of greenish fluid. At 10 A.M. the following day the vomiting ceased, but the pain continued. The bowels did not move. On the second day the pains still continued, the vomiting again returned, there were chills and fever, and some abdominal distention. During the day the pains became more severe and localized below the umbilicus just inside the scar of the previous operation. The bowels did not move. A diagnosis of intestinal obstruction by band or adhesions from previous operation was made. At 3 o'clock that afternoon, about thirty-six hours from the onset, the patient was operated upon. Temperature on admission to the hospital 100.8° F., pulse 108, respiration 24. Face anxious, abdomen moderately distended and rigid. Blood examination showed leucocytes 22,600 and a differential of 89 per cent.

Operation.—A four-inch median incision was made between the umbilicus and pubes. On opening the abdomen immediate search was made for trouble beneath the old scar. Here the omentum was found firmly adherent, but no intestine was adherent or involved. Lifting up a coil of small intestine was followed by a gush of foul fluid, evidently containing feces. This was cleaned away and its source was searched for. A coil of small intestine, ileum, was found bound to the lower lumbar vertebra and perforated. From this was escaping liquid feces. As this coil was so bound down and adherent that any attempt at closure of the opening would be sure to cause stricture, and as the general appearance of that section of the bowel was so bad, resection was determined on. Accordingly, six inches of the bowel, including the area of perforation, was removed, and an end-to-end anastomosis by suture accomplished. There was considerable trouble in controlling hemorrhage from the cut mesentery, owing to its contracted and adherent condition. The lower abdomen was thoroughly irrigated with normal saline solution and sponged out. The wound was closed without drainage. The operation occupied thirty-five minutes, but was accompanied by considerable shock. The boy was put to bed in Fowler's position, was ordered to have nothing by mouth, and instillation of saline per rectum, fifty drops per minute for every alternate two hours. The following morning, March 25, the temperature was 103° F.; there had been some vomiting during the night and the abdomen was greatly distended. During that day the temperature came down to the normal and there was no further vomiting.

March 26.—The general condition remained good, distention seemed some less, there was no vomiting, but a constant desire for water. Temperature during the day normal. During the night restlessness became very great, owing to the constant demands for water. This did not seem to be so much due to thirst as to the idea that something should be taken. During the night the temperature rose to 102° and pulse to 110. The local abdominal conditions seemed to have improved.

March 27.—During the morning the bowels moved several times without aid, the abdomen was now flat, and there had been no vomiting for over forty-eight hours. The patient was now allowed some fluids, and during the afternoon peptonized milk. From this on the recovery was uninterrupted, except for a slight point of infection at the lower angle of the wound, probably due to contact with feces during the operation. At the end of three weeks the boy was apparently entirely well.

Pathological Report by Dr. Blatteis.—Resection of small intestine: 9 cm. long, the perforation is situated along the free margin about 3 cm. from one extremity of resected portion. The margin of the perforation is irregularly circular with a diameter from 3 to 4 mm. and the base slightly indurated. The serous surface of the intestine on the same side as the perforation shows areas of congestion and smaller areas of hemorrhagic extravasation; on the surface opposite the perforation are a number of small suppurative areas. Microscopical examination shows the process to be a simple chronic perforative ulcer of the small intestine. The purulent areas show suppurative and necrotic inflammation of the peritoneal coat and fatty and suppurative infiltration of the muscular coat.

These cases are presented to emphasize this variety of accident and to further draw attention to their frequency.

Twelve years ago the writer reported seven consecutive cases as they came under his observation, and in each the operation proved little more than an antemortem examination. It is with pleasure that I can now present these four cases with practically recovery in all (the patient in Case II. having died from an independent condition); and this result is largely due to earlier diagnosis. Improved operative technique, of course, must be recognized as being a decided factor, but this alone is not enough.

The one distinguishing feature in these cases is the sudden sharp onset of pain accompanied by collapse. Following this is a period of apparent improvement, and it is just here that the danger is, for if these patients are allowed to move about the slight protective adhesions nature has provided will give way and a general peritonitus will result and operation then is less likely to be successful.

The Use of the Seton.—E. Pratt uses in conditions in which a seton is indicated a ribbon of smooth, shiny gum elastic material, at least half an inch, preferably three-quarters of an inch broad. Secondly, he uses an old-fashioned seton-knife, to which the seton is attached. A good fold of skin in the nape of the neck is pinched up, quickly pierced with the knife, and the seton carried right through. The whole operation only lasts a couple of seconds; the ends of the ribbon are tied together so that it cannot slip out, and it is moved to and fro daily. An anesthetic is quite unnecessary, as also is any sterilization or antiseptic washing, beyond ordinary cleanliness, as suppuration is the aim and object of the proceeding. This is the old-fashioned and, in his opinion, the best way of doing it.—*British Medical Journal.*

SELF-REPAIR.

THE therapeutic nihilist loves to point out in support of his faith the innumerable instances of self-repair on the part of the diseased animal organism, thinking thus to discredit artificial therapeutics. But recent scientific work has shown that instances of such repair, far from being destructive of the therapeutic art, really offer an explanation of much of the success attendant upon drug treatment and furnish an incentive to renewed effort looking toward the improvement of our present methods and procedures in fighting disease. This is the view of the matter held by S. J. Meltzer and developed by him in an address before the Association of American Physicians (*American Journal of the Medical Sciences*, July, 1908). According to him the mere existence of self-repair does not exclude the possibility of other means of repair which are not used by nature in her struggle with disease, and the search for these means or their application in fields not naturally provided with them is one of the most important parts of the science and art of therapeutics, which after all is the most important of all the departments of medicine, with the possible exception of hygiene, so far as the welfare of the human race is concerned.

Previous to the modern advance in the study of the phenomena of life in a normal or an abnormal organism, rational therapy consisted for the most part of inactivity, while empiric therapy in many instances degenerated into blind dosing with drugs without any clear notion of their effects upon the organism in health or disease. The study of immunity, however, soon showed innumerable means and methods of self-repair on the part of the body which could be called forth artificially or at other times imitated by the physician and thus answer fully the demands of rational therapy, while attaining the end of empiric therapy as well, which aims at the recovery of the organism from disease without any great concern as to the means employed to this end. The very manifestations which were in the old days looked upon as signs of disease are now employed as therapeutic measures; the artificial hyperemia proposed by Bier in the treatment of inflammation, the example quoted by Meltzer, is enough to prove this point, natural hyperemia, one of the cardinal manifestations of inflammation, being responsible for much of the "tumor, rubor, calor, et dolor" of this pathological condition. Artificial production of leucocytosis is another example of a therapeutic procedure modeled upon a natural process of self-repair; high fever, too, has been produced in animals and in human beings as well, in the hope that this symptom may prove inimical to some pathological process going on in the body.

While it is thus true that rational therapy at present aims more and more to imitate the natural processes of repair, it must not be forgotten that such processes may harm the organism if continued too long or directed only by the blind stimuli of the tissue reactions to injury. This is where artificial rational therapy proves to be superior to the natural self-repair in the organism, and one of the most difficult problems of the newer art of medicine is to decide upon the duration and the amount of self-repair, or imitation of it, that is to be allowed to take place in each case of disease. Meltzer properly says that pain in rheumatism effectively immobilizes the joints, but the joints can be immobilized as well and better by artificial means, while the pain must be relieved to save the patient from its injurious effects upon his organism. Cicatrization of wounds is certainly a reparative process, but when its continuation may diminish the lumina of hollow organs or threaten the functions of an extremity, it is the part of therapeutic wisdom to interfere with nature's effort at self-repair.

Dr. Meltzer's suggestive address sums up the results of the scientific study of pathological processes that has been going on in the last few years. As he says, physiological therapeutics, or the improvement of conditions which the body needs during health, is the only mode of treatment admitted by therapeutic nihilists; the development of medical science, however, has brought forward new methods of treatment, which are modeled along the lines of the processes of self-repair which every organism institutes in response to injury that does not at once destroy its existence. The utilization of these means of treatment constitutes pathological therapeutics, and it is this mode of fighting actual disease that promises to be most efficient in the future.

ACUTE PANCREATITIS.

ACUTE pancreatitis, with hemorrhage into the gland, and often with necrosis of its substance, is followed by a train of symptoms of very violent character, which in the majority of cases quickly lead to the death of the patient. Of late, as the affection has become better known and surgeons are on the lookout for cases of it, the diagnosis of the condition has been made in several instances and immediate operation has saved a good many patients. An exploratory laparotomy is often undertaken in other cases not diagnosed before the operation, and then the striking phenomenon of fat necrosis which accompanies the escape of pancreatic ferments gives the clue to the explanation of the symptoms for which the exploratory incision has been undertaken. From a study of several cases of acute pancreatitis Dr. Bornhaupt, writing in the *Deutsche medizinische Wochenschrift* for July 23, 1908, concludes that more frequent diagnoses ought to be made if certain characteristic signs of the disease be kept in mind in the presence of any acute abdominal symptoms. Pancreatitis of this type is a noninfectious condition and, therefore, there

is usually no fever accompanying it; indeed, the temperature is frequently subnormal. The absence of peristaltic movements and of any marked meteorism speaks against acute intestinal obstruction which simulates most often the picture of acute pancreatitis. Palpation usually gives no distinct signs and so puts one on guard against suspecting any condition with a well-expressed anatomical basis. The pain of pancreatitis is usually epigastric in location, is of extreme intensity, and is further characterized by its persistence in undiminished violence for longer periods of time than is usual in peritoneal inflammations. The presence of sugar in the urine is a sign of great corroborative significance, while the general collapse of the patient from the unbearable suffering is so extreme that operation is usually consented to very quickly and should be in no case long deferred in presence of suggestive symptoms. Prognosis in such cases is favorable only if the gland is but partially diseased and not enough time has elapsed to allow the absorption of a deadly dose of the toxic products of the gland.

The pathology of the affection gives good indications for the procedures to be undertaken in operating. First of all, the toxic secretions must be allowed to escape without further destroying the surrounding tissues; secondly, the infiltration about the gland and consequent pressure upon the celiac plexus must be relieved by properly instituted drainage. With early diagnosis and, therefore, early operative treatment of the affection the chances of the patient to overcome the effects of the acute hemorrhage or necrosis of the pancreas are greatly bettered.

INDICATIONS FOR TEMPORARY GASTROSTOMY.

The object of a gastric fistula as a rule is to permit an individual to be fed through it, either temporarily or permanently. More recently temporary gastrostomy has been advised in cases of acute dilatation of the stomach in which lavage has been of no avail, and in cases of intestinal paresis in which the duodenum is involved. The indications for this operation have been amplified by Lennander (*Deutsche Zeitschrift für Chirurgie,* Vol. 92, No. 4-6), who especially advises it in cases of perforated gastric or duodenal ulcer with stenosis. During the first ten days after operation he gives the patients only 300 to 500 c.c. of bicarbonate of sodium solution by mouth, thus neutralizing the acid gastric secretion. After the tenth day he gives fluid nourishment by mouth and opens the fistula only when the patient experiences a sensation of fullness. At the end of three weeks the tube is permanently clamped, though it is not removed for another four weeks, acting as a sort of safety valve in case distressing symptoms arise. Seven weeks after operation the tube is removed and the fistula is permitted to close, a gastroenterostomy being performed later if symptoms of stenosis set in. In case a general peritonitis is present he also does a typhlostomy, which is of use both to relieve distention and to permit of the administration of nourishment. He believes a temporary gastrostomy should also be performed when, on account of the position or character of the ulcer, one is not sure of his sutures holding properly or when a second ulcer is found which looks as if it might rupture. Lennander prefers Witzel's method of procedure (near the pyloric end of the stomach), since a fistula running obliquely through the gastric wall closes readily after removal of the tube.

Nearly all surgeons are agreed that in cases in which there exists a stenosis and in which a gastric or duodenal ulcer has perforated, not only the wound and peritonitis should be treated, but a gastroenterostomy should be performed at the same time. Lennander's suggestion to perform a gastrostomy and to defer the gastroenterostomy seems advisable, as it is productive of less shock. In cases without stenosis, when one is not sure of the sutures holding when closing the perforation, gastrostomy is advisable, since it aids in healing by preventing gastric contractions, and by permitting lavage, the patient swallowing the water which in turn runs out of the fistula. The operation keeps the stomach at rest.

AMBULANCE SERVICE IN NEW YORK CITY.

No one who has even the most superficial knowledge of the ambulance work of New York City hospitals has any doubt that there is a crying need for reform. This is not said in disparagement of the work of any given institution, for most of them do remarkably well considering their limitations; but it is said in reference to a faulty system and a lack of organization for which no one seems to be directly responsible. The defects of the present situation have been well brought out in an excellent report by the special agent of the Standing Committee on Hospitals of the State Charities Aid Association. In Manhattan and the Bronx there are fourteen ambulance districts apportioned to fourteen of the thirty-one general hospitals by the Police Department. The assignment of these districts has been mainly for the accommodation of hospitals and not for the needs of district population. Consequently few of the hospitals are even reasonably near the center of their districts, and some are on the extreme boundaries. For instance the New York Hospital is at the extreme southern boundary of its district, and St. Vincent's on nearly the extreme northern boundary of its district, thus bringing two large hospitals within four blocks of each other. However, it seems impossible to change this unfortunate arrangement.

At present too much time and effort are consumed in summoning an ambulance. If a policeman finds or is called to attend an injured person, he must ring up his station house, or precinct headquarters; from there the call is sent to Police Headquarters, and thence to the hospital in which district the call is. If all the ambulances are out headquarters is so informed, and the hospital is then directed to send the ambulance that first returns, or the call may be sent to another hospital. Again, it takes time to hitch horse and ambulance together. A few hospitals have the quick hitch arrangements similar to that in use by the fire department, and some have automobile ambulances, but the majority have not.

The Committee recommends that there be established in each borough a central station under mu-

nicipal authority to be directed by a physician appointed under civil service rules; that Manhattan and the Bronx be under control of the Trustees of Bellevue and Allied Hospitals, and Brooklyn under the Commissioner of Public Charities. All ambulance calls would thus be immediately assigned by this central station to the proper district, or, if that district hospital were busy, to the nearest hospital having an available ambulance and a vacant bed. Under this arrangement the Police Department would not have power to assign districts nor in any way to control the operation of the service. This seems an unwise procedure; for the police, owing to their knowledge of general "first aid" principles, are less likely to send in unnecessary summons, and do not make the mistake of well-meaning but over-zealous citizens in sending two or more calls to the same or to several hospitals. The delay caused by finding an officer to telephone a call to the central station would scarcely be commensurate with the chaos created in the service by allowing private citizens to send the summons. Again, if the Bureau of Ambulances should be authorized, as is now planned, to decline to respond to calls which appear from the circumstances to be trivial or mischievous, numerous errors in judgment are sure to be made, and the Bureau might get into serious difficulty amounting even to action in the courts.

To sum up, the conditions for which the Committee seeks relief are: Badly apportioned districts; poorly distributed ambulance service; lack of a central system; the mixture in the system of public and private units; and the cost of this ineffectual service, which is for Manhattan and the Bronx $59,000 annually.

Climatic Treatment of Tuberculous Glands at the Seaside.

For many years the treatment of tuberculosis by means of change of climate and outdoor air included a sojourn in the mountains or at a higher altitude and in a dryer climate than are to be found at the seashore. The reaction, however, against a treatment which carried the patient so far from his business and separated him so completely from his family and all the comforts of his home began some time since, and it has been found that sea air is not so inimical to tuberculosis, especially surgical tuberculosis, as was formerly believed. In France the treatment of tuberculous cases at the seaside has been carried out with a success that has warranted the high expectations of the efficacy of cool, fresh air wherever it can be found. Tuberculous bone and gland diseases, in particular, have been treated on the French coast at sanatoria for children for many years. Henri Richardière in the *Annales de Médecine et Chirurgie Infantiles*, for June 15, 1908, lauds the good effects of sea air combined with sea bathing and local applications of sea water to the enlarged glands in children of all ages. In children under three years the shock and fright induced by forcible bathing in the sea may be unfavorable to a cure, and there are also other patients for whom they cannot be used, such as persons who have pulmonary as well as glandular tuberculosis. Persons in whom the bronchial and mediastinal glands alone, and not the pulmonary tissues, are affected may take the baths with benefit. But an affection of the lungs themselves contraindicates them. For these cases the author believes that it is most beneficial to make use of baths and local applications by compresses of spring water containing chloride of sodium, such as is to be found at Biarritz and Salies-de-Béarn. A combination of sea air with mineral waters, this writer holds, is much more effective in gland cases than a mere sojourn by the seaside. The organic exchanges in the body and the general nutrition are greatly increased by these measures. The formation of urea is increased and the demineralization by uric acid production is decreased. In cases of general atony shown by anemia, anorexia, and general feebleness this combination of treatments is of the greatest value. With compresses saturated with the mineral waters the localization of the applications can be adapted to the position of the involved glands. Warm local douches may also be used. It seems desirable that the efficiency of sea air combined with local saline applications should be still further tested in the vicinity of the extensive seacoast of the United States, that the great opportunities that are presented for treatment of tuberculous gland and bone diseases near our large cities may not be wasted. Treatment of surgical tuberculosis in children has been going on for several years at Sea Breeze, Coney Island, reports of which have already appeared in the Medical Record, and the results obtained are such as to warrant a much wider utilization of the climatic advantages afforded by our very large extent of seacoast on the eastern, southern, and western boundaries of our country.

Tubercle Bacilli on the Clothing of Tuberculous Patients.

It is an interesting fact that such excretions as sputum, urine, and feces are never as objectionable to the individual by whom they are excreted as to other persons. This finds an important illustration in the way in which the tuberculous patients carelessly allow their hands and clothing to be soiled with sputum which produces in another person a feeling of disgust and makes him very careful not to soil his person or belongings with it. Such carelessness of the patients has an important bearing on the spread of tuberculosis in the environment of persons afflicted with the disease, adding to the less avoidable distribution of the bacilli by coughing, sneezing, laughing, etc. Frieberger has endeavored to get experimental evidence of the infectivity of the clothing worn by the tuberculous, obtaining the dust from such clothing by the use of a small vacuum cleaning apparatus, and reports his results in the *Zeitschrift für Tuberculose*, Volume 13, Number 1. These results were not completely in accordance with the popular view of the matter, for very few patients had virulent organisms on their clothing. The important finding consists, however, in the very fact of the absence of such soiling of the clothing, for careful examination of the patients' habits proved that the infectivity or the absence of infectivity of their clothing depended very much upon their habits of cleanliness. Patients in the most advanced stages of tuberculosis, with abundant sputum, had their clothing free of all contamination if their habits were cleanly; even those in the incipient stages had bacilli on their clothes if they were careless in disposing of their sputum. The bedding of patients dying of tuberculosis was found to contain virulent germs. The result of the examination once more calls attention to the necessity of instructing every tuberculous patient, however light his disease may

be, in the care of his person and belongings so as to protect those that come in contact with him. Hospitals, whether caring for tuberculous patients or not, should insist upon the routine disinfection of all clothing of patients on their admission, and a repetition of the process at regular intervals thereafter.

The Pathology of Hemorrhoids.

Few diseases are so general as hemorrhoids, and yet the question of their development and their histological structure has not been finally decided. All the older investigators claimed they were varices, but more recently some have held that they are not mere dilatations of veins, but benign new growths—true angiomata. These differences of opinion led Ruediger-Rydygier, Jr. (*Deutsche Zeitschrift für Chirurgie*, Vol. 91, Nos. 5 and 6) to study the lower portion of the rectum at 200 consecutive autopsies, irrespective of whether symptoms referable to hemorrhoids had been present during life. In the fetus, in the newly born, and in children from five days to eight years of age, he always found the vessels in the submucosa, especially at the lower edge of the internal sphincter and at the mucocutaneous junction, where hemorrhoids usually develop, more numerous than in other parts of the rectal wall. The older the individual, the thicker was the submucosa and the larger and more numerous were the vessels in it. Never was there any sign of new growth. Older individuals showed similar pictures, but when the submucosa was three or four times as thick as the normal, and the vessels were about ten times as wide as normal, he considered the condition a beginning hemorrhoid. He found that many persons had hemorrhoids from a microscopic point of view, although they may never have had any symptoms referable to them. The more marked the hemorrhoid the thicker the submucosa, and the thinner the mucosa over it. When the hemorrhoids were large, he frequently found a round-cell infiltration in the mucosa and skin. As a result of these investigations, Ruediger-Rydygier concludes that hemorrhoids are not new growths, but merely dilated veins—varices.

The Treatment of External Anthrax.

In the treatment of external anthrax most writers advise radical surgical removal of the primary focus, followed by cauterization with heat or chemicals. On the other hand the majority of the cases with favorable termination reported in medical journals during the past few years have been treated conservatively. In the *Deutsche Zeitschrift für Chirurgie*, Volume 92, Nos. 4, 5, and 6, Schwarz reports twelve cases, with only one death, treated conservatively at the university clinic in Halle. He reminds us that the prognosis of anthrax depends upon the development of a general infection; we must therefore judge the various methods of treatment by whether or not they prevent a general infection. He believes that radical measures possess more disadvantages than advantages. Animal experiments have shown that when a general infection sets in, it does so early; thus amputation three hours after injection of the bacilli into a limb does not prevent general infection. This demonstrates that surgical extirpation of the primary focus cannot very well prevent a general infection, for we do not see the patient much before twenty-four or forty-eight hours after infection. In fact, Schwarz believes that the mechanical irritation of the tissues laden with anthrax might easily bring about a fatal general infection, especially when very virulent germs are being dealt with. This danger is present no matter how the primary focus is destroyed, but especially if glands are also removed, a practice resorted to by some. Schwarz believes there is least danger of a general infection when external anthrax is treated by conservative measures, the tissues being left to combat the local infection. Absolute rest, substantial nourishment, stimulants, and protection of the site of infection from external influences by a dressing he considers the best treatment. The correctness of such therapy is proven, he believes, by his successful results.

News of the Week.

The International Congress on Tuberculosis.—The preliminary program of this Congress, to be held in Washington, D. C., September 21-October 12, 1908, is now in press. The section meetings will take place the week beginning September 28, but the exhibition will continue for the entire three weeks, from September 21 to October 12. The program for the week includes two plenary sessions, one on Monday, September 28, at which it is hoped that President Roosevelt will preside; and the other (probably) on Saturday, October 3. Each of the seven sections into which the Congress is divided will hold two sessions daily, except on the days on which the plenary sessions take place.

In connection with the Congress a series of special lectures will be delivered in Washington and elsewhere by eminent foreigners. The names of the speakers and the cities in which they will lecture follow: Bernard Bang of Copenhagen, Washington, October 3, "Studies in Tuberculosis in Domestic Animals and What We May Learn Regarding Human Tuberculosis." A. Calmette of Lille, France, Philadelphia, September 26, "Les nouveaux procédés de diagnostic précoce de la Tuberculosis." Emil Coni of Buenos Ayres, Washington, October 2, "La Lucha contra Tuberculosis en la Republica Argentina." Arthur Newsholme of Brighton, Washington, September 29, "The Causes Which Have Led to the Past Decline in the Death Rate from Tuberculosis and the Light Thrown by This History on Preventive Action for the Future." Gotthold Pannwitz of Berlin, Philadelphia, September 24, "Social Life and Tuberculosis." R. W. Philip, Edinburgh, Boston, October 6, "The Anti-Tuberculosis Program — Coordination of Preventive Measures." C. H. Spronck of Utrecht, Boston, October 7. Andres Martinez Vargas of Barcelona, New York, October 9, "Tuberculosis of the Heart, Blood- and Lymph-Vessels." Theodore Williams of London, Philadelphia, September 25, "The Evolution of the Treatment of Pulmonary Tuberculosis." Maurice Letulle and M. Augustin Rey (joint lecture), Washington, September 30, "La Lutte contre la Tuberculose dans les grandes Villes par l'Habitation; methodes scientifiques modernes pour sa construction." L. Landouzy of Paris, Baltimore, October 5. A. A. Wladimiroff of St. Petersburg, Washington, September 28, "Biology of the Bacillus." N. Ph. Tendeloo of Leiden, "Collateral Tuberculous Inflammation."

The Koch Foundation for Combating Tuberculosis.—The German Emperor has given $24,000 to the Robert Koch Foundation for resisting the spread of tuberculosis. This donation completes the

$100,000 that Andrew Carnegie stipulated should be subscribed before his gift of a like amount, made last winter, should become available. The sum of $76,000 was raised shortly after Mr. Carnegie made his announcement, but there the subscriptions stopped until the Emperor decided to make up the balance.

Disease Among the Aborigines of Alaska.—Reports come from Alaska through a special charge to the Grand Jury sitting at Juneau that tuberculosis, trachoma, and other diseases are spreading to such an extent among the Indians that their very existence is threatened. From the data furnished it would appear that within a few decades, if the mortality of the race continues as in the recent past, there will be no longer any native inhabitants to perform the needed labor which the progress and development of the country demand. The statistics taken from a typical settlement of the natives, show a greater mortality than that of any other primitive race which has come in contact with Anglo-Saxon civilization. An appended report by Army Surgeon Paul Churchill Hutton states that he doubts if any country in the world can show such a percentage of tuberculous natives, and the mortality from this disease is really terrible. He proposes that Alaska be divided into sanitary districts and that sixteen sanitary officers be appointed. He also suggests that an intelligent Indian inspector be appointed for each town having 200 or more inhabitants, and that each Indian inspector study under the regular inspector and disseminate his knowledge among his own people.—*Charities.*

Cholera in Russia.—The center of virulence in the cholera epidemic in Russia has been transferred to Rostov-on-the-Don, where thirty-one new cases and ten deaths were reported on August 17. From the Province of Astrakhan sixty-one new cases and twenty-one deaths were reported on the same day. The cholera is now working its way down the Black Sea along the Caucasus coast. Its appearance at Gelenjik, south of Novorossysk, has been announced.

Care of the Feeble-Minded.—The British Royal Commission on the care and control of feeble-minded persons has issued a report, in which the American system of dealing with these unfortunates and the management of the institutions where they are assembled are highly spoken of. "In most of the States visited by us," the report says, "the practical measures adopted for the solution of this problem were more advanced and more successful in character than anything attempted in Great Britain." With regard to lunatic asylums, the impression of the commission is that in America these institutions are better designed, more cheaply constructed, and more successfully managed than the majority in Great Britain.

A Test of the Iowa Contagious Disease Act.—The Hamilton County, Iowa, Board of Supervisors has been served with notice by a physician of Stratford, that he will bring suit at the October term of court, claiming $165 for services rendered in contagious disease cases. The board allowed him $60 for these services, and he refused it. The case will be a test of the new Iowa law passed last winter, which, it is held, makes the county liable for physicians' fees in every case of contagious disease they attend.

Medical Fees.—According to a new fee-table adopted by the Everett, Mass., Medical Society, the charge for ordinary visits in the daytime will be $2, but night visits will be $3. Visits in cases of contagious diseases will be $2.50; visits in consultation, $5; vaccination at home $2, at office $1; each additional member of family for vaccination, $1; administering anesthetics, $3 to $5.

A New Medical Office Building in Denver.—Plans have been filed in Denver for the construction of a steel and concrete fireproof six-story building at the corner of Sixteenth street and Court place, for the exclusive use of physicians. Special features of the building will be a fully equipped operating room, a medical library of 15,000 volumes, and an assembly room for meetings. About 100 physicians can be accommodated.

Meeting at Craig Colony.—Dr. W. P. Spratling, Medical Superintendent of Craig Colony, has invited representatives from all the N. Y. State Hospitals for the insane and from the Charitable Institutions generally to meet at Sonyea, on Thursday, September 3. A medical program has been arranged for the day, while the evening will be given up to entertainment. Dr. Spratling will lecture on the types of epilepsy and show living pictures of epileptic manifestations.

More Brain Storms.—A captain in the United States army recently shot and killed a man, putting all the bullets from his revolver into his victim's body, while his brother held the crowd at bay by threatening to shoot any man who attempted to interfere with the captain's sport. These two men are to be tried in Long Island City, and the defense of "insanity" is already announced by the counsel. Of course there will be medical experts on hand at the trial to coach the lawyers on both sides and to testify for and against the accused. There may not be as many as at the Thaw trials, and those that are there will probably not be so well paid—in promises and expectations—for there is less wealth in the family of the prisoners: but the need of reform in medical expert testimony will no doubt be again exemplified.

Medical Automobilists Permitted to Speed.—The physicians of Orange, N. J., will, it is said, be immune from arrest while breaking the speed laws on condition of voluntary appearance at court and explanation of the occurrence. The cars will bear a flag having the insignia of the Physicians' Automobile Club, and the police have been notified not to arrest the driver of any such car, but simply to take the number for future action in case the owner does not appear later without a summons.

Inspection of Kitchens.—The Health Department of St. Louis has decided to undertake a systematic inspection of the kitchens of hotels and restaurants, and of groceries, butcher shops, and bakeries, special attention being paid to screening, ventilation, plumbing, and the condition of the floor.

Disinfection of School Books.—Following an inspection of the libraries of the public schools the Orange, N. J., Board of Health has decided to disinfect every book in the schools between now and the time the schools open on September 8. There were more than the usual number of cases of scarlet fever in the schools last year.

Books for the Blind in Esparanto.—The fourth international Esperanto Congress, which met last week in Dresden, passed a resolution to print a number of Esperanto instruction books and translations in raised characters for the use of the blind.

Dr. Manton M. Cornish of Dallas, Texas, has been appointed assistant quarantine inspector of the port of Galveston.

Dr. Rufus I. Cole, of Johns Hopkins University, has declined an invitation to succeed Dr. George

Dock in the Chair of Medicine at the University of Michigan. It is said that Dr. Cole will become Director of the new Rockefeller Research Hospital in New York City.

A New Medical College in Atlanta.—The Hospital Medical College is the name of a new medical school which, it is announced, will be opened in Atlanta in October. At a meeting for reorganization, held August 8, Dr. J. H. Powell was elected president of the new school and Dr. Gates Hathcock, vice-president; Dr. Charles Field was chosen dean. The faculty consists of seventeen members.

Contagious Diseases in Chicago.—According to the weekly bulletin of the Chicago Health Department, during the week ended August 14, 181 cases of contagious diseases were reported. There were 41 cases of diphtheria, 35 of scarlet fever, 19 of measles, 25 of whooping cough, and 37 of tuberculosis. With the exception of measles and tuberculosis there were fewer cases than in the preceding week. The Isolation Hospital is now empty.

Southern Minnesota Medical Association.—At the annual meeting of this Association, held at Owatonna during the first week in August, the following officers were elected: *President*, Dr. O. F. Way of Claremont; *Vice-Presidents*, Drs. W. S. Wood of Blooming Prairie, and Hugh McGaughey of Winona; *Secretary and Treasurer*, Dr. Adams of Elgin. The next annual meeting will be held at Winona.

Obituary Notes.—Dr. Peter Evans Hine of Raleigh, N. C., died August 13. He was born July 28, 1828. He was graduated at the N. C. State University in 1849, and with his medical degree at the University of Pennsylvania in 1852. He served as surgeon in the Confederate service throughout the Civil War, and at its close retired to his farm in Craven County. In 1872 he resumed practice in Raleigh. He was president of the Medical Society of North Carolina in 1890, and was Surgeon-General of the State from 1878 to 1883.

Dr. Frederick R. Cummings of Concord, N. H., died August 9, from pyemia, at the age of 35 years. He was born in Nashua and was a graduate of the Harvard Medical School in the class of 1898.

Dr. John T. Irion of Paris, Tenn., died August 10, at the age of 71 years. He was a graduate in medicine of the University of Nashville, and practised for many years in Paris, being for a number of years president of the city board of health. He retired from practice fifteen years ago to become editor of a daily newspaper.

Dr. O. T. Pratt, of Los Angeles, died on August 5 while listening to a political address by Judge Alton B. Parker. He had practised in Southern California for many years, having moved from Compton to Los Angeles about ten years ago to form a partnership with his brother.

Dr. Rufus B. Whitehead of Elizabeth, N. J., died suddenly on August 20, at the age of 36 years. He was a graduate of the College of Physicians and Surgeons in this city in the class of 1893. He was surgeon to the General Hospital of Elizabeth, and for a time served as police commissioner of the city.

Dr. Ira B. Cushing of Brookline, Mass, died August 15, at the age of 62 years. He was born in Providence, Ill., and was graduated from the Hahnemann Medical College, Philadelphia.

Dr. S. G. Dillan of St. John's, Mich., died suddenly on August 12, at the age of 60 years.

Dr. William H. Webster of Dayton, Ohio, died suddenly on August 10. He was born in 1870 and was graduated from the Pulte Medical College, Cincinnati, in 1874.

Dr. George H. Smith of Brooklyn, New York, died of septicemia following an operation wound, on August 20. He was born in Milton, N. Y., in 1843, and was graduated from the Homeopathic Medical College in this city in 1869.

Correspondence.

THE CARDIAC ATMOSPHERE OF BAD NAUHEIM.

Bad Nauheim, July 29, 1908.

To the Editor of the Medical Record:

Sir:—I have been spending a month here, observing the treatment of cardiovascular disease by the methods here employed, and have found many things to interest me in regard to this subject.

I find a great number of Americans who come here year after year for the adjustment of their heart and blood-vessel disorders, and who are inclined to believe that their welfare depends upon their annual pilgrimage. Thirty thousand persons come to Nauheim every year, and a great proportion of these come for heart troubles. The result is that Nauheim represents in the aggregate greater experience in the physical treatment of heart trouble than any other place in the world. Here the attention of everybody is on this subject, and not the least part of one's impression is gained from the patients themselves. Unlike many other European cures, there is almost a total absence of any kind of gayety. So many of the guests are seriously ill that the expression of an impending attack of angina can be seen wherever a number are gathered together.

The plan of treatment has been but little changed since the time of August Schott, and one is impressed with the extreme care with which the baths and exercises are prescribed. This is founded not upon the idea of making much of the treatment, but because ever-occurring experience is constantly showing that satisfactory results can be obtained only in this manner.

The question that is so often asked as to whether like results cannot be obtained in America, must be answered in the affirmative, but at the same time the greater difficulty must be acknowledged. It is the difference between a government providing an institution for many persons and an individual providing an institution for himself. The physician here prescribes the baths and exercises and the government provides the bathhouse and attendants, the parks and music, and the 30,000 guests trained by long years of instruction in the hygiene of heart trouble provide just the right mental atmosphere. It is the same difference as between learning a foreign language at home and learning it where everyone speaks the language.

I have seen in New York City results in similar cases just as good as those attained at Nauheim, but they were paid for by much greater expenditure of labor on the part of the physician and self-denial on the part of the patient. It is much easier to get up at half-past six in the morning for a bath or exercise when one knows that at seven o'clock a band will play and one will meet plenty of people that one knows, than it is in New York when the streets are deserted and everybody one knows is in bed.

When we once begin in America to establish cures, there is no doubt the same conditions will finally develop, and I believe the time will come when we shall draw patients from Europe. The vitality of American medicine is such that in the next fifty years it ought to reach a point that will leave other countries far behind.

Louis F. Bishop, M.D.

54 West Fifty-fifth Street, New York.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ECHOES FROM SHEFFIELD—ROYAL COMMISSION ON THE FEEBLE-MINDED—CHILDREN'S HOSPITAL, OUT-PATIENT DEPARTMENT.

London, August 7, 1908.

The British medical meeting is over and a number of members have returned. Many more made Sheffield the starting place for their autumn holiday. Those who are here give a glowing account of the meeting, especially from the viewpoint of amusements and entertainments provided, for it must be admitted most of them look upon the excursion as a prolonged picnic rather than an opportunity for serious work. The gen-

eral meetings only interest members, except the addresses, which were well attended. The university contributed largely to the success, inasmuch as its fine buildings were able to accommodate all the sections. This was a "great comfort" to many, who were glad to look in at more than one discussion. On former occasions the sectional meetings have been scattered over the town where the association met. In such conditions the enthusiast in one branch was perhaps satisfied, but even the most devoted specialist may be glad to put in an appearance or meet friends in sections which have less claim on him. So, too, he may rejoice in the opportunity of seeing and hearing celebrities in various departments of science.

The new out-patient department of the Children's Hospital was opened on Tuesday and is quite a model. It has been built by means of a fund amounting to £50,000 placed in the hands of trustees by Mr. W. W. Astor. Patients enter from the street level. In front of them is a lift to take perambulators to the basement. On the left, in a long, separate room, are five cabins, into which pass cases suspected to be infectious, one being for the doctor in attendance. Close by are two halls, with smooth, polished floors, walls tiled to a considerable height and painted above, flooded with light and air from skylights and open roofs. The latter is for new patients. There are also four consultation rooms and an inquiry office. The dispensary is in the basement, but there are no steps. An inclined plane takes the patients down in their perambulators and up to another street when supplied. Between 400 and 500 is the daily attendance. As the hospital is still in debt, one may be excused for asking whether too much has not been spent on this elaborate building for the out-patient department.

The report of the Royal Commission on the Feeble Minded has just appeared as a blue book of over 500 pages. As the evidence taken extends to seven similar volumes and as ninety-six recommendations are made in regard to England and Wales, only the most diligent student of the subject will have food for his mental digestion for some time to come, and those who regard themselves as authorities must seriously consider the conclusions and proposals put forth. The number of the mentally defective persons is not certain. Estimating it from certain parts of the country, the commissioners think it may be 150,000, of which 66,000 are in need of care in their own interests or for the public safety. The first problem, therefore, was to devise the machinery for bringing them under supervision. They recommend that there shall be one central authority, to be called the board of control, consisting of medical experts and barristers; also that special local authorities shall be appointed to deal with their defectives under the supervision of the central board, all institutions for the care of these defectives to be licensed by the central board and to be visited at least twice a year.

The annual exhibition was held in a separate building at some little distance from the university, but was, I am told, very well attended; in fact, one informant says he was inconvenienced by the crowd at one point. Surgical appliances were the favorite section of this gentleman, who found a number of novelties, especially in the wealth of *x*-ray and electrical apparatus, displayed. Pharmaceutical products were, as usual, abundant and most of the leading manufacturers represented. I suppose these exhibitions contribute to their sales and so are commercially successful. The exhibitors seem to have been well satisfied with the arrangements, for they presented the general manager with a clock, the acting manager with a gold ring, and his assistant with a case of silver spoons.

A much more interesting exhibition was the pathological, though it was not so well attended; but those who went say it was an example to be followed if the association is to retain a reputation for serious study as well as business aptitude. It was held in the pathological department of the university and there was a good catalogue of the specimens, more than 500 in number. The committee which collected this little museum is to be congratulated. It seems a pity the collection should be so soon distributed.

The hospitality of the North is proverbial, and Sheffield has equaled, if it has not surpassed, its reputation. The visitors all testify to this, and Sheffield itself seems well satisfied, though one curious little grumble appears in the local press. The citizens are said to think that some of their energetic practitioners and professors should have been put on the committees newly appointed. Only one, Dr. Sinclair White, has been thus recognized, although so many worked hard for the success of the meeting. I doubt if the editorial wisdom has in this matter penetrated the thoughts of the local profession. Service on the committees can be no pleasure, and most of them know that the ruling clique desires to retain full control in every detail.

The popular lecture by Mr. Edmund Owen was an excellent lesson for the Sheffield workmen if they would have listened to it, but, as was freely said, something is wrong with them, for they stayed away and instead of an audience of artisans there was one—and that not a large one—of ladies and gentlemen in evening dress. The local workman's enemy is dust, and Mr. Owen's subject was "Dust and Disease." It was illustrated by lantern slides, given in simple language, and ought to have attracted those most interested. He ventured on a prediction that when the association next meets in Sheffield the deadly dry grinding will be as much out of date as rush lights or tinder boxes. Smoke, he said, was a form of dust, and Sheffield still accustomed itself to a large share. It was not fit that furnaces should foul the air with poisonous fumes. Many deaths were caused thereby and the time would come when it would be as serious an offense to foul the air as it is to pollute a river.

The president's reception was an event of which Sheffield is proud. About 1,500 guests assembled, among them the association being well represented. The rooms of the Cutlers were all decorated in lavish style. The banqueting hall was transformed into a drawing room, where two concerts were given, and the lower hall was used for a dramatic and musical recital.

About 200 members accepted an invitation to visit Buxton—so renowned a spa for rheumatism. The railway facilities gave them three hours to become practically acquainted with its waters and therapeutical appliances. But above half the time was consumed otherwise, for the local reception committee conducted them first to a hotel, where they had provided luncheon, and by the time the speeches were concluded and a stroll through the lovely gardens taken the time for the return train was fast approaching.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

IMMUNIZATION OF CATTLE AGAINST TUBERCULOSIS—REMOVAL OF A BULLET FROM TEMPORAL LOBE—TORSION OF SEMINAL CORD—EFFECT OF NICOTIN UPON ADRENAL GLANDS—LARGE NEVUS OF THE AURICLE—A NEW INTESTINAL ANASTOMOSIS BUTTON.

VIENNA, July 30, 1908.

A FEW days ago Professor Heymans of Ghent was the guest of the Royal Society of Physicians and spoke before that body on the various methods of immunization against tuberculosis. He uses the following immunizing method in cattle: One milligram of the tubercle bacilli of the human type are enclosed in a small sac dipped into collodion and put into a gelatine capsule. The little sac is introduced under the skin of the animal, a small incision being made for the purpose. The gelatine is rapidly dissolved after the wound has been closed and the sac forms a very good diffusion membrane enclosing the bacilli; the latter obtain all the foodstuff necessary for their growth, the tube allowing the passage of such material, and the products of their growth act as immunizing bodies in the organism of the animal. Within forty-eight hours an exudate consisting of polynuclear leucocytes forms about the membrane, and somewhat later there is formed about it a capsule of connective tissue. In the course of ten to eighteen months the bacilli die in such a capsule and become completely disorganized. This procedure was originated after many experiments with the behavior of the little bag in the animal organism. If 0.5 cm. of tuberculin is placed into such a bag and the latter is then dipped into salt solution the tuberculin diffuses into the fluid surrounding the sac, which fact may easily be shown by inoculating animals with that fluid. A bag filled with tuberculin and introduced under the skin of an animal likewise produces the specific reaction in that animal. If glycerin bouillon inoculated with the tubercle bacilli is placed into the bag and the latter is then submerged in some culture medium and kept in the incubator the bacilli develop in the usual fashion. After four or six weeks, when no more bacilli can be demonstrated in the bag, the contents may be injected into a tuberculous animal and the latter reacts to this injection just as it would to the use of tuberculin in the same fashion. Healthy animals in whom the little bag has been placed and allowed to heal over, tubercle bacilli being part of the contents, begin to react to tuberculin injections three to

six weeks later; the sensitiveness to such injections continues for four to six months and then disappears. If animals that have been immunized in this fashion are given one large dose of tubercle bacilli by mouth or are fed daily during three weeks on small quantities of bacilli they do not become infected with tuberculosis although this is the usual event in the control animals treated in exactly the same way except for the immunization with the bag. Accordingly, the immunized animals show a certain resistance to infection with tuberculosis. To the tuberculin test about ten per cent. of the healthy inoculated animals give a positive reaction and the autopsy shows six to ten per cent. of them as tuberculous. If the little bag is placed under the skin of tuberculous animals there takes place a slow tuberculization of them, many of the cattle showing diminution or even total disappearance of the tuberculin reaction; the autopsy often shows regressive changes in the tuberculous processes, so that a certain curative effect must be supposed to be produced by the above described immunizing method.

Professor Schnitzler has succeeded in removing a bullet from the right temporal lobe of a young patient. The girl was one and a half years old when she was wounded in the left temporal region by a revolver bullet. A few months ago intense headache localized to the right temporal region appeared and the *x*-ray examination showed the presence of a foreign body in the right temporal lobe of the cerebrum. The position of the bullet was then studied more exactly by repeated examinations with the *x*-rays, lead plates and tapes being placed on the skull to find out the relations of the bullet to the surface landmarks. Schnitzler then bared the right temporal lobe by an osteoplastic operation, but at first was unable to locate the bullet. He then availed himself of a procedure which he used with success some eight years ago in operating for a foreign body in the cerebellum. He introduced a silver wire into the lower corner of the wound, passing it as nearly as possible in the direction of the projectile, closed the wound, and then made several additional examinations with the *x*-rays, which, of course, gave the relations of the silver wire to the bullet. After six days the skin and periosteum flap was again turned down and an attempt was made to find the bullet by means of its relations to the silver wire. But this attempt was likewise unsuccessful, for large incisions had to be avoided in order to spare the brain as much as possible. Schnitzler then introduced a piece of silver wire bent into a bow into the right temporal lobe and this time the *x*-ray picture showed the projectile surrounded by the curved end of the wire. At the third operation the bullet was finally located and removed. The flap healed in very nicely, and the patient, who showed some paralytic phenomena confined to one side directly after the operation, recovered completely and is now in perfect health.

Dr. Borszeky of Budapest operated upon a patient suffering from a spontaneous torsion of the seminal cord. The patient was 29 years old and was attacked with an intense, stabbing pain in the left half of the scrotum after having jumped from a high ladder; he was also very dizzy and became nauseated. On examination in the hospital, the scrotum was found to be the size of two fists, while the patient was extremely pale and appeared very much prostrated. Operation was quickly decided upon and when the tunica vaginalis was divided about half a liter of dark-colored serum was evacuated. The cord was found to have been twisted over 180°, the testicle was discolored and appeared bluish, while several veins of the cord were the thickness of the finger. The thickest veins had to be resected. The testicle completely recovered from the injury and at present, seven months after the operation, the man is in perfect health. The speaker confessed that the mode in which this very rare condition arose in the case which he had reported could not be surely established, and the real causation of the torsion still remains an open question of pathology.

Mansfeld, also of Budapest, had studied the effect of nicotin upon the adrenal glands. He experimented with cats and has shown that the increase in blood pressure which follows the administration of nicotin is caused by the stimulating action of the drug upon the secretion of the gland; the content of the blood in the active principle of the gland is thus increased with the well-known effect of a rise in the blood pressure. A portion of blood taken a few minutes before the administration of nicotin shows no adrenalin present, while at the time of the greatest rise in the blood pressure the blood may be shown to contain the pressure raising principle of the gland. After the extirpation of both adrenal glands the administration of nicotin had no pressure raising effect and the blood of such animals did not show the presence of adrenal principle after the administration of the drug, the Ehrmann reaction being negative. The author concludes that the adrenal glands are innervated not by the sympathetic but by some autonomous nerve. Although Goldzieher of Budapest thinks that the narcosis itself has some effect upon the adrenalin content of the blood, yet the results obtained by Mansfeld throw some light upon the pathological significance of nicotin in producing arteriosclerosis; they are certainly of sufficient interest to prove stimulating to the workers in this field of research, which is especially devoted to the physiology and the pathology of those important organs—the adrenal glands.

Professor Ladislaus Fleischmann of Budapest had occasion to operate on a case of elephantiasis of the auricle. This patient was a sixteen-year-old boy who had a tumor of congenital origin which occupied the left auricle and was quite unusual in shape as well. Microscopic examination proved it to be a nonpigmented nevus. As the tumor was benign in character, Dr. Fleischmann did not consider it necessary to remove the whole auricle and selected the following procedure: The portion of the tumor which was situated behind the auricle and which presented the appearance similar to the surface of the brain because of the numerous folds and convolutions, he removed almost *in toto*, thus leveling the tissues until the normal contour of the auricle was obtained. The deep infoldings of the epithelium which lined the convolutions and the fissures of the tumor were not removed and they were thus able to provide for the new epithelial covering that was necessary to make up for the defect produced by the operation. All the tissues which rose beyond the cartilage of the auricle were likewise removed and the skin edges sutured together. A few defects were covered over by skin grafts which were obtained from the patient's leg.

Professor Ferdinand Klug tried to explain the old problem of the immunity which the stomach and the intestines enjoy from being digested by their own juices. His experiments showed that the worm Ascaris is protected from being digested by the juices of the intestines by the fine cuticle which covers its surface as well as its intestinal tract. The inner portion of the gastric mucosa as well as the mucous membrane of the small intestine prevent the digestive action of the gastric juice and of trypsin. The extract obtained from the intestinal mucosa of pigs according to the method of Weinland consists almost wholly of mucin. This extract is capable of interfering with the digestive action of both gastric juice and of trypsin, the raw extract being much more powerful in this inhibitive action than the same extract after being boiled. The cause of this difference must be sought in the fact that after the boiling the extract becomes much less soluble than the raw preparation. The small intestine and the stomach are thus protected from self-digestion by the mucin which is present in their secretions, this explanation having already been offered and supported by Schiff. The experiments could not show the presence of any special antiferments. The mucin is not digested by pepsin-hydrochloric acid nor by a solution of trypsin; it is furthermore not a readily diffusible substance, and because of this fact it holds the active secretions away from the mucous membranes of the stomach and of the intestines, and this action suffices to preserve the organs from self-digestion.

Dr. Lieblein of Prague has constructed a new absorbable intestinal anastomosis button. It is made out of paracasein which is hardened by formalin and is called in that condition "galalith"; it has all the advantages claimed for the Murphy button and is in many respects superior to the latter. The galalith button is quite similar to the Murphy button in form and in the mechanism of its action with the exception of minor changes, such as the omission of the spiral spring. The two lateral springs in the male portion of the button which fit into and firmly clasp the female half are constructed out of "new silver." This button weighs much less than the Murphy button and in addition is absorbable. This new galalith button has been used in nineteen gastroenterostomies performed for carcinoma of the stomach, for ulcer with acute hemorrhage from the stomach, twenty-six buttons having been used altogether. One of the patients operated upon for acute gastric hemorrhage died of anemia; the anastomosis was not accompanied by any untoward reaction. All the other cases recovered from the operations very satisfactorily. Three resections of gangrenous intestine in strangulated herniæ were performed, the new button being used; one of the patients died quite independently of the results of the anastomosis, while another showed a small perforation in the afferent part of the intestine, which may have caused his death, but could not be completely traced to the button. The new button is especially recommended in place of the Murphy button in the anastomosis required in the performance of gastroenterostomy.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 13, 1908.

The Immediate Treatment Demanded in Certain of the More Serious Ocular Lesions That Are Frequently First Seen by the General Practitioner.—Frederick E. Cheney says that it not infrequently happens that the family physician, from one cause or another, is obliged temporarily to assume the responsibility of a case that is of undoubted gravity, and the question of the immediate and proper treatment required under such circumstances is naturally an important one. A case in point is acute glaucoma, the only curative treatment of which is operative. This is essentially a disease of middle life and old age. Given a congested, reddened eye, and enlarged inactive pupil, rapidly failing vision, pain and nausea, there is little chance of error in making a diagnosis. The immediate treatment demanded is the use of the myotic until arrangements can be made for an iridectomy. It is well to begin with a 2 per cent. solution of pilocarpine nitrate, instilling two or three drops into the eye every half-hour. A stronger myotic, such as eserine sulphate, may be used if necessary. With the improvement in vision it is well to reduce the frequency of the myotic. Hot fomentations are sometimes of value in adding to the comfort of the patient. Iridectomy should not be delayed for more than three or four days. Iritis is an extremely grave condition when treatment has been delayed. The symptoms of iritis most constant and to be depended upon are the pinkish zone of injection surrounding the cornea in connection with a contracted pupil that reacts sluggishly or not at all to light. Added to these one will probably find a discoloration of the iris and a greater or less degree of supraorbital pain. The essential treatment is the use of a mydriatic of sufficient strength and frequency to dilate the pupil as widely as it is possible to dilate it. Under this treatment many, if not all, of the existing adhesions will usually give way and there is little danger of fresh adhesions taking place if the pupil is kept dilated by a weaker solution of the agent used. In using the stronger solutions of atropine it is important to have the patient keep the end of the finger firmly pressed upon the inner angle of the eye for three or four minutes after each instillation. This will prevent in a great degree the escape of atropine by way of the tear passage into the nose, and the consequent dry throat and other symptoms of poisoning. A 1 per cent. solution is none too strong, and should be instilled three or four times a day. The application of leeches to the temple is at times of great value. Blindness from ophthalmia neonatorum in a very large proportion of the cases means blindness from neglect. The Credé method is undoubtedly of great value, but causes considerable temporary irritation. A 25 per cent. solution of argyrol is practically nonirritating, and to drop four or five drops into the conjunctival sac of every newborn babe would be a simple and a very efficient means of prevention. This treatment, together with the frequent cleansing of the eyes, if it can be thoroughly and systematically carried out, will, with rare exceptions, insure a perfect recovery. The following suggestions regarding perforating wounds of the eyeball are in the nature of early emergency treatment: First, to lessen the chances of infection, the lids and their immediate neighborhood should be thoroughly cleansed and the conjunctival sac irrigated with a boric acid or some other mild solution. Second, a 1 per cent. solution of atropine should be instilled three or four times at five-minute intervals for the reason that iritis will develop in at least 80 per cent. of these perforating injuries. If the anterior chamber is evacuated, the pupil will not dilate until it is reestablished. Third, some simple nonirritating ointment should be placed on the inner surface of the lower lid and the eye then bandaged. Fourth, Epsom salts, calomel or other active cathartic should be given. Fifth, a leech to the temple is good routine practice, and at times of the greatest value.

General Therapeutics of Gastric Affections.—Maurice Vejux Tyrode says that diseases of the stomach are treated along the lines of general therapeutics which are applied to other organs. Two opposite principles lie at the bottom of symptomatic therapy, *i. e.*, rest and exercise, or decrease and increase of functions. The agents at command include four general classes: First, the physical, as exercise, massage, electricity, baths, etc.; second, the psychical, as suggestions in the hypnotic or hypnoidal states and under waking conditions; third, the dietetic, including both qualitative and quantitative changes in the diet; and fourth, the medicinal. In order that these agents may be judiciously and effectively employed, an accurate diagnosis must be made. He then reviews briefly the physiology of the stomach and takes up the treatment of the different gastric functions when at fault. Great care should be exercised in not confounding grave troubles as ulcer and cancer, with hyperacidity, as cases have come to his observation with carcinoma when the diagnosis of the attending physician was nervous dyspepsia.

New York Medical Journal, August 15, 1908.

Vaccine Treatment of Atrophic Rhinitis (Ozena).—Ross Skillern and E. Burvill-Holmes report two cases treated with a vaccine from the combined culture of a serum from a pure culture of the bacillus of Abel. Injections were given in the arm at first twice weekly, no inflammatory reaction following. After two weeks there was, in the first case, a marked diminution in the size of the crusts and the nasal secretions appeared to be much thinner and more miscible with water. A gradual diminution of the fetor occurred. At this stage the child developed a disease resembling scarlet fever, which brought the treatment to a sudden close. About two months later they learned that the child was as bad as ever. The mother of the child asked that treatment be again instituted as soon as possible. The promising results in this case prompted them to test the method in a case which had proven hopeless to other forms of treatment. The patient was a woman, thirty years old, who was given fourteen injections with improvement; then a sudden change for the worse set in, and the disease gradually began to assume the old condition; the crusts became larger, the fetor reappeared, and the patient became nauseated. About three months after the cessation of the treatment she reappeared, requesting treatment, saying she never felt so well as when under the vaccine treatment. If pure cultures of the *Bacillus mucosus capsulatus* could be obtained they believe that the successful treatment of atrophic rhinitis would, indeed, be a thing of reality.

Pneumonia; One Method of Treatment.—E. P. Tompkins reports the case of a young man, a fine specimen of manhood physically, hale, hearty, robust, of good habits, about twenty years old, and who had never been sick before. This was a case of pneumonia. His temperature was 103° F. and he was semi-delirious when the physician was called, and this condition rapidly advanced to active delirium. The pulse was full and bounding, face flushed, slight, hacking, suppressed cough, with frothy expectoration which soon became streaked or rather mixed with blood. The physical examination showed only slight dullness over the seat of pain. Half a dozen bricks were placed on the fire and a kettle of water was put on to heat. When the water was boiling and the bricks about red hot, they were placed in the water and allowed to remain until ebullition ceased; each brick was then wrapped in a cloth, and placed in the bed alongside the patient's body, and over him a number of blankets. Over the region of pain was put a flannel cloth saturated with oil of turpentine, and over this a folded newspaper. Internally was administered a tablet of calomel and sodium hydroxide, half a grain each, one every two hours till four doses were taken. Alternating with this, hour by hour, a tablet containing aconite, two minims; tartar emetic, one-fortieth of a grain; ipecac, one-eighth grain; morphine sulphate, one-twentieth of a grain, to be given till further notice. In ten minutes the patient was trying to throw the covers off, and it took the combined efforts of four men to hold the delirious patient in bed. The next day the patient was resting quietly, free from pain, the temperature was reduced to 101° F. The pulse was slower, the purgative had acted, and his general condition was satisfactory. In a well-heated room his clothing was changed, the bed also, and he ate a little milk toast and soft cooked egg. Twenty-four hours later his pulse showing decided softening and lessened size, the aconite and tartar emetic tablet was discontinued and one containing digitalis, nitroglycerin, and strychnine substituted. In seventy-two hours from the time he was taken sick his pulse and temperature were normal, his appetite good, sleep was natural, and he proceeded to an uninterrupted recovery. He was advised to remain indoors a few days longer, and in a week was back at work. The most noteworthy point in the case was the tremendous rapidity with which severe symptoms developed from a condition of perfect health, emphasizing the fact that treatment if effectual in cutting short an attack—and he was convinced that in the great majority of cases pneumonia can be aborted—must begin early.

Journal of the American Medical Association, Aug. 15, 1908.

Diverticulitis of the Sigmoid.—G. E. Brewer reports diagnosis was made and operation performed before the occurrence of rupture, and the only one recorded in which the patient survived two operations for this condition. In the first attack there was a localized abscess, but the a case of diverticulitis of the sigmoid, the first in which

patient recovered and remained well over five years. In such cases Brewer would lay down no general rules of technique, but if the diverticulum is large, attached by a broad base or covered with a plexus of enlarged vessels, the safest method, he thinks, would be extraperitoneal drainage, as chosen in the case reported. If, from the situation, this is impracticable, he suggests packing with gauze and leaving it in place for from 48 to 72 hours or until firm adhesions have formed, then removal of the gauze and free opening of the abscess, allowing it to drain through the channel thus formed.

Gastric Ulcer and Cancer.—F. B. Lund remarks on the difficulties that are often met with in the differential diagnosis of benign gastric and malignant growths: "In certain cases of indurated ulcer of the stomach the diagnosis between benign and malignant disease may be impossible, even with the abdomen opened. These are the early cases, in which the diagnosis of early cancer is important, as enabling thorough removal. These cases, broadly speaking, fall into two classes: 1. Indurated ulcers (usually of the lesser curvature), which are movable and free and may be benign or malignant. Here, even if the tumor is benign, gastroenterostomy is often unavailing and partial. 2. Indurated ulcers of the pylorus often extending from the duodenum and adherent to the pancreas or left lobe of the liver. These are usually benign; excision is difficult and gastroenterostomy is safe and should usually be performed rather than excisions. In Class 1 excision should be done regardless of laboratory findings. In Class 2 the laboratory findings are important and usually reliable. The responsibility of leaving a tumor which may be malignant is so great, however, that all diagnostic aids should be invoked, and in case of doubt excision, though at some risk, may be performed. The surgeon must decide in each case whether the risk lies in performing excision or leaving a tumor which may be malignant."

Therapeutic Immunization in Mixed Infection.—A. P. Ohlmacher discusses the problems which confront the physician who would apply in practice Wright's method of therapeutic bacterial immunization. He enumerates the organisms usually found in mixed infections and states that in dealing with them it is necessary to follow the events in the more chronic suppurations by bacteriological analyses from time to time and to modify the inoculations to correspond with the changes in the bacterial flora of the pus in case the therapeutic response is not satisfactory. In dealing with tuberculous diseases in which a mixed infection is demonstrable by the culture test it is proper, he asserts, to combine the inoculations of tuberculin with vaccines of one or more of the complicating bacterial species. This procedure is conducive to good results in treating the suppurations following tuberculous urinary infection, adenitis, synovitis, or osteitis. Syphilis and a concurrent or a secondary infection with pyogenic bacteria is another condition in which, according to Ohlmacher, therapeutic bacterial immunization finds useful application.

Intestinal Anastomosis.—F. B. Walker points out the defects of the present methods of intestinal anastomosis; all except the McGraw elastic ligature are done on a wide-open gut and are essentially septic operations. The ligature method—the simplest and cleanest of all—does not complete the anastomosis for three or more days, and is therefore unsuited in cases in which other communication does not exist. The method he describes and illustrates can be carried out, he says, by one pair of hands and combines the advantages of other methods without their defects. It is based on the closure of the gut during the operation by means of a removable purse-string suture, on serous apposition by a continuous through mattress suture inserted from the outside of the gut, and on the withdrawal of the purse-string suture after the suturing is completed, leaving an open lumen. The technique for both end-to-end and lateral anastomosis is described and illustrated.

Ulcer of the Duodenum.—William J. Mayo considers the differential diagnosis between duodenal and gastric ulcer and states that in duodenal ulcer the pain and tenderness, as a rule, extend from the mid-line to the right; aggravation induced by food comes on several hours after a meal, and the patients suffer from a peculiar "hunger pain" when fasting. Unlike gastric ulcer, duodenal ulcer rarely undergoes carcinomatous degeneration. The surgical treatment of chronic duodenal ulcer will usually consist of gastrojejunostomy, preferably by the "no loop" method. The small esteem in which surgery of the stomach and duodenum is held by many professional men, and the bad results reported, have been largely due to mistakes in diagnosis and unnecessary operations performed where no ulcer existed. So far as possible, he has traced patients with duodenal ulcers operated on in 1906-7. One hundred and nineteen patients were operated on in 1906-7, and 106 were traced. Of these 87, or 82 per cent., were cured; 10, or 9.5 per cent., improved; and 6, or 5.7 per cent., unimproved, making cured and improved 91.5 per cent. The operative mortality in the whole number of cases was 2.8 per cent.

The Lancet, August 8, 1908.

Human Tuberculosis and Cattle Tuberculosis; Investigations as Regards Ninety-seven Norwegian Farms.—Birger Overland recapitulates some of the best known facts of what has been ascertained as to the relation between tuberculosis in man and in cattle. He determined to ascertain if possible whether it is a rare or frequent occurrence on their Norwegian farms for cattle and man to infect each other. During his examination he used the following scheme of questions: When was the live stock tested? How many animals had you then? How many of these reacted to tuberculin? Have any instances of disease occurred among the occupants which may have been tuberculosis? If tuberculosis has been made out in the cattle the following questions are put: Has the animal been bred on the farm, or has it been purchased; if so, how long ago? How old is the reacting animal? Have any of the milkmaids been tuberculous? Have children drunk unboiled milk? Has any child shown suspicious symptoms? In cases of tuberculosis in the occupants the following are the questions asked: Has the patient had anything to do with the cowhouse; when and for how long? If he may have been infected through milk, were other sources of infection possible? He makes up the results in four groups. 1. Farms where no positive tuberculin test in the live stock has occurred, and where he has not been able to find cases of tuberculosis among the occupants. 2. Farms with no positive tuberculin test in the live stock, but with cases of tuberculosis among the occupants. 3. Farms with positive tuberculin test in the live stock, but with no cases of tuberculosis among the occupants. 4. Farms with positive tuberculin test in the live stock and with cases of tuberculosis among the occupants. His material was procured from 97 farms with 1,157 total head of cattle. His contention was that *tuberculosis in man and tuberculosis in cattle have a certain relation to each other*, as reaction in cattle on farms where human tuberculosis has been traceable occurs nearly three times as frequently as on farms where this disease was not found.

The Treatment of Abscess of the Appendix.—Archibald W. Cuff believes that they should always endeavor to remove the appendix at the same time that they open and drain the abscess if there are no grave contraindications. Among the disadvantages of leaving the appendix even for a short time is the unpleasant way in which in many of these cases a sinus, or even a fistula, is left. Again, these wounds heal less kindly. It should be borne in mind, too, that a second operation is no slight ordeal to a patient who has been through a painful and perhaps an exhausting sickness. In view of these considerations he urges the advisability of always removing the appendix at the first operation whenever feasible, and this will rarely not be the case.

Use of Selected Lactic Acid Bacilli and Soured Milk in the Treatment of Some Forms of Chronic Ill-Health.—George Herschell says milk curdled with the lactic acid bacillus is a most wholesome food, and can be used with benefit in such diseases as anorexia nervosa, phthisis, hyperchlorhydria and achylia gastrica; chronic duodenal catarrh, chronic gastritis and malignant disease of the stomach. Among other conditions in which this bacillus, either as a pure culture or as curdled milk, may be given to patients is abnormal fermentation in the intestine, causing ill-health either by local irritation or by autointoxication. It may also be given to render the gastrointestinal tract aseptic previous to an operation upon it. It may be used in some forms of constipation, especially the atonic form, which is due to defective peristalsis dependent upon muscular weakness or upon deficient innervation. Anything up to a pint of curdled milk may be given during the day. From a dietetic point of view all cases are divided into three groups, the acute, subacute, and the chronic. In the acute cases it is a good plan to commence by suppressing all food except solution of sugar of milk in water, solution of malt extract in water, and the culture of the bacillus which they were giving. In the subacute cases he advised eliminating meat from the diet, which should consist of yolks of eggs, butter, bread, potatoes, milk puddings, fruit, and vegetables. In the ordinary chronic cases he quotes the rules taken from Combe. Avoid all substances which can act as culture media for proteolytic baccili. Avoid all meat fat. Limit the patient to fresh butter and yolks of eggs. Avoid all high meat and game.

British Medical Journal, August 8, 1908.

Treatment of Some of the Severer Forms of Headache.—Wilfred Harris says that clinical grouping according to the situation of the pain or its character is altogether unsatisfactory and misleading, and he has arrived at an anatomical classification of his own after careful consideration. Of the causes within the cranial cavity, the true neuralgic headaches, such as the neurasthenic, or that produced by dazzling of the eyes, various emotions, a thunderstorm, etc., are best relieved by rest and antineuralgic remedies, such as phenacetin, pyramidon, and this class of drugs. The toxemic headaches are often caused by constipation and sluggish livers; unless a regular daily habit of the bowel is established by means of daily saline laxatives, the headaches will recur. To relieve the pain of migraine, remedies which will lower the intracranial pressure must be applied. The available remedies may be divided into two classes: 1. Local, trephining and opening the dura; lumbar puncture; leeches to the scalp; fomentations, hot bottles, or icebag to the scalp and neck. 2. Indirect, by lowering of the general blood pressure, nitroglycerine, and the nitrites; cardiac depressants; purgation, diaphoresis, hot baths. He believes the operation of trephining for the relief of migraine is justified in those severe cases which frequently recur and in which the patient is prostrated for one or more days every week. But before this is seriously thought of leeches to the scalp should be applied, and ten grains of Dover's powder given, with a hot drink containing one-sixth of a grain of pilocarpine. The patient should be kept lying down, warmly wrapped up, so as to promote perspiration. Under this treatment he has seen great and speedy relief.

The Dangers of Calmette's Ophthalmo-Reaction.—Three cases are reported by T. Harrison Butler to show that the dangers of Calmette's reaction are very real, and that, as the reaction is by no means conclusive, it is hardly a justifiable method of diagnosis. Personally he has abandoned the method, and is now employing injections of old tuberculin to help to decide the question as to whether a disease is or is not tuberculous in character.

Berliner klinische Wochenschrift, August 3, 1908.

Fulguration.—Arndt has studied the effect of fulguration, the method introduced by Keating-Hart for the treatment of malignant disease. He concludes that deep narcosis is not needed in using fulguration, if care is taken not to expose the skin to the effects of the sparks or to protect exposed skin by dry compresses. The fulguration of the skin, of the muscles, and of the bones produces hardly any effect upon the action of the heart or of respiration. Fulguration of the dura and of the brain is followed by no immediate harmful results, while small irritation may be avoided by the use of short sparks. Fulguration of the organs in the thoracic cavity may be used only after certain protective measures have been taken, the heart reacting with arrhythmia and the blood pressure falling immediately after the beginning of the application. Especially marked were the symptoms of irritation when carbonic acid gas was used for cooling purposes. The direct application of the sparks to the digestive organs and to the bladder cause marked peristalsis, but the abdominal walls or dry compresses efficiently protect these organs from any indirect influence. Pieces of normal or tumor tissue examined immediately after fulguration showed no change except a little superficial necrosis.

Relations of the Adrenals to the Kidneys.—Reicher says that it has been shown that the adrenal substances are increased in the blood and the adrenal organs are hypertrophied in marked cases of nephritis; in animals, total or partial nephrectomy or the ligature of the renal arteries causes increased secretion on the part of the adrenal glands. Siegel has shown that actual nephritis may be produced in animals by exposing the bared kidneys to the effects of cold, bilateral disease being usually produced. Reicher's experiments have shown that the partial submersion of an animal in icewater leads to an increased content of the blood in adrenal substances immediately after the experiments, and a few days later albumin and casts make their appearance in the urine. The exposure to cold seems to act as a very potent stimulus to the adrenal glands, and the increased secretion of the latter causes active contraction of the kidney vessels; the active principle of this secretion has a selective effect upon the kidney, the oncometer showing diminution in its volume and therefore contraction of its vessels long before the general blood pressure is raised. The increased content of the blood in adrenal substances may explain the origin of some kidney affections leading, as it does, to long-continued ischemia accompanied by poor nutrition of the kidney substance. Three cases of arterial sclerosis with beginning nephritis have shown the presence of an increased amount of adrenal substances in the blood. Neither these few cases nor the animal experiments justify any final conclusions as to the etiology of nephritis, the fact, however, that there exists an interrelation between the activity of the adrenal glands and the kidneys seems to be proven by the above results.

Deutsche medizinische Wochenschrift, July 30, 1908.

The Advantages of Pfannenstiel Incision.—Zimmermann says that all chronic inflammations of the pelvic organs ought to be dealt with by the abdominal route in order that any complications from the appendix may be treated. Such operations may now be much more readily advised since the introduction of the Pfannenstiel incision, which saves the patient from the dangers of the classical laparotomy, the chief of which is the postoperative appearance of hernia. The main points of the Pfannenstiel incision consist in a transverse incision at the upper limit of the pubic hair dividing the skin and subcutaneous tissues in a curved line; the fasciæ are incised in the same manner and the two free borders dissected upward and downward; the recti are separated longitudinally and the transversalis fascia and the peritoneum are divided in the same manner. The introduction of a speculum or retractors into the wound made in this fashion gives a very good view of the gynecological field for operation, while the region of the cecum and the appendix is likewise within easy reach. The advantages of the incision are: the scar falls in the hair line or in the natural fold of the skin above the symphysis; contractions of abdominal muscles lead to diminution and not to increase in the size of the wound, and coughing or vomiting are not as apt to produce hernia; there is direct access to the organs to be treated and the absence of much retraction and of pulling on the peritoneum diminishes the operative shock; herniæ are extremely rare occurrences in the postoperative history. The one disadvantage of the incision, the danger of subfascial suppuration in the event of wound infection, simply calls for perfect asepsis in operating. The incision, however, is not adapted to dealing with large solid tumors or any other conditions that occupy the large pelvis. Affections confined to the small pelvis are the ones best handled by the Pfannenstiel incision.

Pyelitis.—Scheidemandel says that pyelitis appears much more frequently as a primary affection than is usually thought. It is more frequent in women than in men. It is marked by a sudden rise in temperature, and by attacks of pain affecting the right side more often than the left; objective examination shows the presence of pus and bacteria in the urine, which findings may appear only intermittently. The fever continues for five or six days and is followed by a lytic or a critical fall, thus simulating lobar pneumonia. A second attack usually follows after a few days' intermission, this time involving the side which has previously been unaffected. The disease is probably due to the colon bacilli by ascending infection from the anus. Recovery follows after two or three attacks, the chronic form of the disease being a rare sequel. Of especial interest is the premenstrual form of pyelitis appearing three days before that function takes place. The therapy consists in rest in bed, the administration in abundance of slightly diuretic decoctions, warm compresses, light diet and the use of narcotics when called for by intense pain. The prolonged use of hexamethyleneamin, salol, etc., is to be condemned. The disease deserves to be better known among physicians, many cases being diagnosed as appendicitis ovaritis, etc.

Treatment of Cardiac Diseases by Thermal and Massage Applications.—Angelo Velpe has for twenty years studied the treatment of cardiac disease in connection with the administration of the Baths at Naples. He concludes from his experience that we cannot hope for a cure in organic cardiac affections, but that marked relief may be obtained in many conditions. The cardiac functions may be temporarily or permanently modified. Thermomineral alkaline baths and massage together present advantages over any other form of treatment, in that the heart does not become accustomed to them. The application should be most carefully controlled by the physician. It increases the systole of the heart, lowers blood pressure, lessens the obstacles to the heart action, and improves the circulation. In well compensated lesions with hypertrophy it will do harm by increasing the energy of the systole. The pulse is differently affected in different affections, being slowed or increased in rapidity according to the heart condition. The treatment has little influence on arrythmia.—*Annali di Elettricità Medica e Terapia Fisica.*

Book Reviews.

State Board Questions and Answers. By R. Max Goepp, M.D., Professor of Clinical Medicine at the Philadelphia Polyclinic; Assistant Visiting Physician to the Philadelphia General Hospital. Philadelphia and London. W. B. Saunders Co., 1908.

This large volume contains a selection of the questions asked at some of the State Board Examinations, with answers to the same. With regard to the questions, while doubtless they are well chosen, a selection is not of much use to any candidate; he would like to see the omitted questions, or at any rate to know what proportion the selected ones bear to the whole. Perhaps the omitted questions are those most difficult to answer, or even to understand; for examination questions are not always as lucid as the answers are expected to be. Many of the answers are satisfactory, some being taken bodily from other sources (*e.g.* from the Medical Record). But some of the questions are only partially answered, some of the answers are inadequate, and some, we fear, would not be accepted even by a State Board Examiner. For example, a poison is defined as "any substance producing deleterious effects upon the animal organism"; this would include a brick-bat or an automobile. "Expired air contains no oxygen or only a very little." Na_2CO_3 is given as the formula for sodium bicarbonate. Several of the chemical equations do not balance. The rate of the blood current in the capillaries is given as two inches a second. "Boron is one of the constituent elements of the human body." The pneumogastric nerve is said to be "exclusively motor." "The foramen ovale of the heart carries the blood which enters the left auricle from the inferior vena cava, to the right auricle." Those who might use this compilation with safety (that is, with discrimination) are the ones who do not require it; while those who need such assistance as the volume affords are liable to be misled, perhaps fatally.

Manual of Surgery. By Alexis Thomson, F.R.C.S. Ed., Assistant Surgeon Edinburgh Royal Infirmary; Surgeon to the Deaconess Hospital, Edinburgh; and Alexander Miles, F.R.C.S. Ed., Assistant Surgeon Edinburgh Royal Infirmary; Surgeon to Leith Hospital. Vol. I, General Surgery; Vol. II, Regional Surgery. Second Edition. Revised and enlarged; with 203 illustrations. Philadelphia and London: J. B. Lippincott Company, 1908.

To write a serviceable manual of surgery in two small volumes, properly culling the important parts from the vast material of the theory and practice of this specialty, is no easy task. It is, therefore, a pleasure to see it so successfully accomplished as is shown in the "Manual of Surgery" of Drs. Thomson and Miles. The first volume shows original distribution of material; repair, conditions interfering with repair, surgical bacteriology, the temperature in surgical diseases, and the methods of wound treatment preceding the discussion of inflammation. Suppuration, ulceration, gangrene, chronic infections and tumors are then considered. The rest of the first volume treats of the diseases of blood and lymph vessels, of nerves, of bones and joints and the structures in relation to these. A special chapter on the deformities of extremities closes the volume. Volume II is devoted to regional surgery, about one-third of the book being given up to surgery of the abdomen and of the pelvis. The rest of the volume treats of the surgical diseases of the head, neck and chest. Most of the chapters are introduced by short, but ample, sketches of the surgical anatomy of the parts considered; the clinical pictures of the affections are clearly defined; treatment is given a great deal of space, specific instructions and suggestions prevailing under this heading. The work shows careful attempt to bring it up to date, the etiology of syphilis, the diseases of the pancreas, the nature of shock, Bier's hyperemic method of treatment, etc., being discussed in the light of recent advances in our knowledge. On the whole, these volumes form as useful and as compact a manual of surgery as we have seen.

Climate. By Robert De Courcy Ward, Assistant Professor of Climatology in Harvard University. New York and London: G. P. Putnam's Sons, 1908.

Works on climatology have always been disappointing so far as therapeutics is concerned, and this one is no exception. Professor Ward has compiled a mass of data of extreme value to those who are interested in climate by itself, but curiously little of it has a practical medical bearing, and that little is stated in such general terms as to be of no value to apply to particular invalids, and some of it is incorrect. As a textbook on classifications of climates it is excellent, and the chapters devoted to the characteristics of the zones give the facts with accuracy, but when the author describes the life of man he is on debatable ground. It is clearly stated that the plants and animals adjusted to the conditions of one locality cannot thrive or even survive elsewhere, and he gives some of the details whereby survival is possible in certain adversities. Yet in only one place is it casually intimated that the same law applies to the various types of man, each of which is also adjusted to its climate. That is, every climate is perfect for all living forms which have become moulded to it by a long process of selection. Elsewhere and throughout the work the impression is given that climates must be studied in relation to mankind in general, and that some are better than others. No greater mistake is possible, though it is the old view of climatologists. There is little in the book as to the recent anthropological studies which prove that the characteristics of races are evolved by climate killing the unfit and selecting the fit, and that, for instance, the apparent laziness of tropical natives and energy of those in colder places is a necessary character thus indirectly evolved—not as a direct effect of climate on the individual. Indeed it is known that a tropical climate at first has a stimulating effect upon northern types, which later become lethargic from exhaustion, while the native race is lethargic from normal functioning.

The discussion of hygiene of the zones does not completely accord with what is known of the infections which have been so fatal in the past, nor with the recently discovered facts as to the physiological effects of light and heat. The author speaks of the blood becoming "more dilute" in the tropics, whereas it is known that some of the most deplorable results are due to increased specific gravity. He speaks of beriberi being a tropical disease, though some of its worst ravages have been in Manchuria. In the discussion of tropical diseases, opinions are expressed which also are not in accordance with the results of tropical studies. It is said that "the best preventives of plague are pure air and modern sanitation," yet it is known that fleas are the sole carriers, and that if they are prevented from biting plague is never contracted. The advice that "many elderly persons and those who are overworked may find rest from nervous tension in the enervating climate of the tropics" is dangerous in view of the high mortality rate among elderly and exhausted persons who go to the tropics.

The Reduction of Cancer. By the Hon. Rollo Russell. Longmans, Green & Co., 1907.

This essay is written with the intention of proving that cancer is due to the excessive use of tea, coffee, alcohol, and "probably of potted and chemicalized meats, pork, and other flesh." The following are the chief arguments advanced, stripped of verbiage and repetitions: (1) Wild animals are free from cancer; domestic ones occasionally subject to cancer as the result of overfeeding and improper diet. (2) Natives of wild and primitive countries living on simple diet are free from cancer; those of highly civilized countries are most affected in proportion to their consumption of tea and coffee; (3) the rich, who drink more alcohol (*sic?*) tea, coffee, and eat more meat, are subject to cancer more frequently than the poor in the same localities. (4) Cancer is becoming more frequent with the increasing abuse of tea, etc.

The few quotations above cited give a fair idea of the fabric of the argument. The conclusion is: Cancer can be reduced by excluding tea, coffee, etc. As well might one argue that tuberculosis is due to coffee, etc., for it occurs in the same or nearly the same geographical distribution as cancer. Domestic animals are affected; wild ones free; civilized races affected, wild ones free, etc., etc. The book cannot be taken seriously by a scientific reader, but it preaches a good doctrine—moderation in diet—and therefore cannot do harm.

Nouveau Traité de Médecine et de Thérapeutique, Publié sous la Direction de MM. P. Brouardel et A. Gilbert. Maladies des Artères et de l'Aorta, par H. Roger, Professeur à la Faculté de Médecine de Paris. Médecin de l'Hôpital de la Charité; A. Gouget, Professeur agrégé à la Faculté de Médecine de Paris, Médecin des Hôpitaux; et E. Boinet, Professeur de Clinique Médecale de l'École de Médecine de Marseille, Médecin des Hôpitaux. Paris: J. B. Baillière et Fils, 1907.

The present volume forms the twenty-tourth of Brouardel and Gilbert's systematic treatise on medicine and therapeutics. In it are considered at great length, with full bibliographical references, etc., the diseases of the arteries and the aorta, from the viewpoint of the physician. Two-thirds of the book, which comprises 472 octavo pages, are devoted to the aorta. Of this space one-half or more is occupied by the subject of aneurysm of the aorta; the rest by aortitis, acute and chronic. Much attention is paid to the pathological and experimental sides of the subject, but the clinical aspect is not neglected. The sections on treatment are very brief, however, as may be expected when dealing with such subjects as arteritis and aortitis. The volume forms a fit companion to the others already issued in this series of monographs.

Society Reports.

BRITISH MEDICAL ASSOCIATION.

68th Annual Meeting, Held in Sheffield, July 24-31, 1908.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page* 343.)

SECTION OF MEDICINE.

Thursday, July 30—Second Day.

Etiology of Degenerative Changes of the Aorta.—Dr. G. NEWTON PITT of London, in opening this discussion, alluded to the circumstance that advanced degeneration might be present in a small part of the aorta while the rest was healthy; this was probably owing to a local infection; also to the fact that with the aorta healthy the peripheral vessels might be atheromatous or *vice versâ*. Atheroma and arteriosclerosis were quite distinct diseases and much confusion had resulted from not observing this distinction. Atheroma of the aorta was not a single process but the result of a number of different causes and processes. The changes might result from infection from within, but it was unusual to have aortic changes from the acute infectious diseases, the protection of the system was so good. Pyrexia was often associated with the development of atheromatous changes in the aorta. High blood tension and strain were possible causes, but at least half the cases of aortic degeneration were not associated with hypertrophy of the heart. In cases, however, with other primary causes these might be secondary causes. Atheroma in the pulmonary artery was practically limited to cases such as those of mitral stenosis, in which the pulmonary arterial blood pressure was increased. Reference was made to the tendency of atheromatous patches to increase. It was a question whether the changes in the intima were primary or secondary. In any case they were probably protective. The intimal nutrition might be disordered by changes occurring in the middle coat and adventitia, especially those affecting the vasa vasorum. In regard to the influence of old age, atheroma occurred occasionally in the young, therefore, this could not be the only cause; many of the most aged had perfectly healthy vessels; it seemed to be a question of greater frequency of exposure to infection with longer life. Inoculation with organisms failed to produce arterial changes in animals below a certain weight, thus system changes seemed to be a necessary antecedent. It was not at present possible to classify the causes of atheroma of the aorta. Taking the quite early cases, occurring in the early years of life, most were due to syphilis and usually to congenital syphilis. Of other degenerative changes of the aorta in addition to atheroma fatty changes were of importance, but these were not more frequent in the aged than in the young. It was as yet a moot point whether they developed into atheroma. Changes due to the administration of adrenalin and to increased pressure in the aorta experimentally produced, were quite distinct from atheroma; they were of the nature of acute calcareous degeneration of the media. Little was known definitely as to the influence of sex and race in developing atheroma. Occupation seemed to have influence either from strenuousness or sedentary habits. Diet and defective metabolism was one of the causes in the development of atheroma—the toxic effect was probably the main factor.

In regard to aneurysm of the aorta, syphilis rather than atheroma was probably its most important cause, syphilis being traceable in 70 or 80 per cent. of the cases. The process of aneurysm formation was the yielding of a scar tissue following on a gummatous deposit. Many cases of aneurysm showed no evidence of high arterial pressure, but the fact that aneurysm occurred in the lower animals showed that syphilis was not an absolutely essential factor. Reference was made to the experimental production of degeneration of the middle coat of the thoracic aorta by pressure on the aorta in the abdomen. As life increased the lumen of the vessel increased due to a degeneration (not atheromatous) of the middle coat. Acute aortitis might occur from infections which might lead later to atheromatous changes. The significance of pyrexia in such cases was great. As to the experiments with adrenalin the change was not purely the result of high pressure, as the necrosis of the muscle fibers and even the formation of aneurysmal patches occurred if a nitrite were given at the same time. True atheroma had not yet quite clearly been set up by experiments although the inflammatory changes produced simulated it. By using nonvirulent organisms and giving a long time for the experiments, however, changes resembling those of atheroma had been found in the media. Atheroma did not occur with the specific fevers, but in some slowly infective process as by *Staphylococcus albus* or the *Bacillus coli* was a more likely cause, plus the changes of senescence.

Professor C. J. BOUCHARD of Paris gave figures obtained from his researches on 4,000 cases of chest disease examined for the purpose of ascertaining the relations of angina pectoris. Among these 83 had angina, and among them he expected to find that the majority were syphilitic but in 12 only was it definite. There were 12 cases of angina in 261 syphilitics, more than 4.5 per cent., and 71 cases in 3,739 nonsyphilitics, being less than 2 per cent. Syphilitic lesions of the large arteries might be influenced by treatment; he had observed in 7 cases the disappearance of an aortic murmur during treatment. The method he adopted was the injection of mercurial solutions preferably in the neighborhood of the affected artery.

Sir LAUDER BRUNTON of London referred to the influence of a general predisposition and a local cause in arterial degeneration. In the absence of any scientific basis for our treatment of the state of defective metabolism, gouty and other, it was necessary to fall back on the observed effects of medicaments in treating arterial degeneration and its results. Atheroma of the larger arteries was a distinct condition and was apparently producible by experiment. Not only adrenalin but also barium, digitalis, and tobacco might give origin both to rise in blood pressure and also directly to aortic changes. It was important, therefore, to keep the blood tension low. In India the blood pressure had seemed to him to be lower than in this country; and in Canada, according to his observation, higher. The way to keep the blood pressure down was by giving a mixture of a nitrate and a nitrite. In elderly people high arterial tension often manifested itself by epistaxis which could itself be prevented by such treatment. He gave the medicines in doses of one-half to 5 grs. of nitrite of sodium to 20 grs. of nitrate thrice a day. If it were desired to reduce the pressure quickly nitroglycerine was preferable. Potassium iodide with saline and mercurial purgatives were also to be given, and by these and cognate measures the changes of old age might, he believed, be warded off, and life prolonged for five or ten years.

Sir JAMES BARR of Liverpool gave an account of his views of the pathology of aortic degeneration. While recognizing the other causes that had been alluded to he attached very special importance to the influence of intermittent strain in producing aortic degeneration. There should be but little difference between the systolic and diastolic blood pressure to ensure or promote the preservation of the arteries. The influence of heredity was also of great importance.

Dr. W. RUSSELL of Edinburgh thought it was not necessary to have degenerative changes in the aorta even when there was great difference between the systolic and diastolic pressures as in aortic incompetence. He adhered to the infective origin of atheroma. He was extremely glad that the term arteriosclerosis had been taken exception to.

Professor W. OSLER of Oxford repudiated the implication of Sir Lauder Brunton on his country. He would himself say that the British blood pressure was higher than the Canadian, but it was not an opinion based on

definite statistics. The influence of acute infections in the production of aortic lesions was the chief point in the discussion. It was probable that too much importance was attached to small aortic lesions in typhoid, scarlet fever, measles, and pneumonia. In rheumatic fever the matter was different, for the endoaortitis produced was serious. The only infection that was of much moment in producing aortic lesions was syphilis. Its importance was in three directions: in producing aortic insufficiency in young men, in being the frequent cause of angina pectoris in young men; and in the production of aneurysm in young men. This was due to a split in the intima over a small area as a result of sudden strain. The other types of aneurysm occurred in older people and were atheromatous in origin. The importance of the subject was wrapped up in the early and thorough treatment of cases of syphilis.

Sir JOHN BROADBENT of London referred to the relation of atheroma and aneurysm and to the effect of syphilis, but considered that intermittent strain was responsible for a certain number of cases apart from syphilis. The rarity of degenerative changes in the aorta in chronic interstitial nephritis was very significant. The changes in the peripheral vessels in Bright's disease were not degenerative but hypertrophic. The vessels mainly affected were those in the brain. The experimentally induced strain was hardly comparable, he thought, with the prolonged strain as seen for example in chronic Bright's disease. The vasa vasorum were of great importance in this relation: in syphilis endoarteritis obliterans affected these vessels, and the intima became diseased because it was furthest from the blood supply. In the toxic cases the toxins were probably directly destructive of the tissues they had affinity for. The primary change was degenerative and manifested by a large amount of cellular infiltration. In some cases vessels might be found penetrating the media, an abnormal phenomenon which was probably the result of the attempt at repair of a degenerative process following an infective process.

Dr. NEWTON PITT, in reply, thought the important point was that when once a spot of aortic damage occurred from any cause that that became vulnerable to infections. It was to be remembered that aneurysm was much more common in herbivorous animals than in carnivora; this had significance on the question of the influence of nitrogenous diet. The chief cause of aneurysm on herbivora was the presence of parasites.

Dr. WILLIAM RUSSELL of Edinburgh then read a paper on "The influence of the arterial wall in the clinical hemomanometric estimation of blood pressure," emphasizing the influence of a thickened ventricle in giving high manometric readings.

Prevention of Pleural Adhesions.—Dr. OTTO GRÜNBAUM and Dr. W. O. PITT of London read this paper, entitled "An Attempt to Prevent the Adhesion of the Pleura after Inflammation." The method adopted, the use of air failing to prevent adhesions, was to inject a harmless and slowly absorbed fluid into the pleural cavity. Such a fluid was found in the liquid paraffin of the British Pharmacopœia. Staphylococci and aluron were injected into the pleural sacs of guinea pigs, producing purulent inflammation, and after that the paraffin seemed to diminish the formation of adhesions.

Sir JAMES BARR of Liverpool said he had used the method for several years and, as he believed, with good results. He would, however, inject air at the same time.

Dr. W. RUSSELL asked if recovery of the pleural surface without adhesion could occur in the presence of the destruction of the serosa.

Dr. NEWTON PITT said he had seen absolute recovery of the pleural surface—becoming smooth and without adhesion—after empyema.

Dr. O. GRÜNBAUM said that his experience had been that complete recovery occurred in joints after pneumococcic inflammation.

Friday, July 31—Third Day.

Treatment of Gastric and Duodenal Ulcer by the Internal Administration of Antilytic Serum.—Dr. E. C. HORT of Torquay read this paper. A fair if rather rough estimation of the activity of any particular sample of antilytic serum could be arrived at by observing the effect of its application to any open wound. A summary was given of twenty-five cases of gastric and duodenal ulcer treated with the serum together with strict avoidance of a slop diet and rectal feeding.

Pneumothorax.—Dr. M. PARRY JONES of Derby read a paper on some cases of pneumothorax, arguing that the prognosis even in association with tubercle was not so grave as was frequently considered.

Human and Bovine Tuberculosis.—Dr. NATHAN RAW of Liverpool read a paper on human and bovine tuberculosis with special reference to tuberculin, maintaining that from 10 to 20 per cent. of the tuberculous lesions in the human subject were set up by the bacilli of bovine tubercle. His views were based on a study of 4,000 cases of pulmonary tuberculosis and 1,600 cases of so-called surgical tuberculosis. His previously expressed views as to the different seats of invasion by the human and bovine types of the tubercle bacillus were developed. He argued for the treatment of different forms of tubercle by different varieties of tuberculin, particularly of human tubercle of the lungs with bovine tuberculin and of human surgical tubercle (really, he maintained, a bovine tubercle), with human tuberculin.

The Class System in the Home Treatment of Tuberculosis.—Dr. J. H. PRATT of Baltimore, Md., communicated a paper containing the results obtained by treating pulmonary tuberculosis in the home by the "class" system. The chief rule of the "class" was that the patient should spend the entire day in rest in the open air and in many cases sleep in the open air. The essential feature of the "class" system was a weekly meeting, when the patients were seen and examined by the medical man and the record books kept by the nurse in the intervals were examined.

A Misleading Cardiac Murmur.—Dr. J. E. SQUIRE of London read a paper on an exocardial murmur often misinterpreted, a cardio-respiratory murmur of no importance in regard to the health of the subject, but of especial interest in relation to life insurance.

Treatment of Sciatica.—Dr. J. BRINDLEY JAMES of London read a paper on the treatment of sciatica by the injection of sulphuric ether combined with either cocaine or morphine into the sciatic nerve, beginning with doses of 5 minims of ether and 2 minims of a 5 per cent. solution of cocaine or 3 minims of solution of morphine and gradually increasing the dose. A needle 2½ inches long was used after marking out the position of the nerve by measurement and touch. It was important to notice that unless the patient shot out his leg at the time of the injection the nerve had not been touched.

Dr. RUPERT WATERHOUSE of Bath read a paper on syphilitic arthritis.

Constipation.—Dr. A. F. HERTZ of London read this paper, on giving a lantern demonstration of radiographs of the passage of bismuth-meals through the different parts of the bowel.

Dr. WILFRED HARRIS of London gave a cinematograph demonstration illustrating typical gaits, tremors, elicitation of various reflexes, etc., in cases of nervous disease.

Dr. GODFREY CARTER of Sheffield described a case of apyrexial typhoid fever.

SECTION OF SURGERY.

Friday, July 31—Third Day.

The Technique of Cancer Operations, with Reference to the Danger of Cancer Infection—Mr. CHARLES RYALL in this paper said that cancer was a spreading infective

process, the cells containing the elements of infection. From the primary growth the disease invaded surrounding tissues, and also disseminated to distant parts. The cancer cells in their behavior resembled infective bacteria. Secondary malignant foci might result from contact infection, or from distant implantation, and these processes could be set in motion by operation, as exemplified by suture-scar infection, nodular infection within the area of the wound, and diffuse or brawny infection. Hence the need of special technique in cancer surgery. When exploratory incision proved a growth to be malignant, and excision was forthwith carried out, fresh instruments, towels, bowls, etc., were then employed, and the surgeon's hand sterilized *de novo*. The ideal method of removing a cancerous growth was to excise a shell of healthy tissue enclosing the cancer and the nearest lymphatic glands. Gentleness of manipulation was to be seduously cultivated, in order to avoid squeezing cells into uninfected tissues; and the curette, if used for scraping away necrotic cancerous material, should never be applied beyond the region of the growth.

Painful Displacement of Ribs.—Prof. Depage of Brussels read this paper. The patients were women in whom the eleventh or the tenth rib pressed on the iliac crest, or one overrode the other, and thus gave rise to iliac pain, usually on the right side. The symptom might be mistakenly ascribed to nephroptosis, appendicitis, or salpingitis, and unsuitable operations might consequently be performed. The pain was probably due in different cases to compression of nerves, to periostitis, or to peri chondritis. The best early treatment was by selected gymnastics continued for a year, and corsets were to be forbidden. In four patients whose suffering was intolerable resection of the anterior ends of the ribs was performed—of the eleventh rib alone in three cases, and of the tenth and eleventh ribs in the other case, a perfect cure resulting in all.

Some Cases of Hematuria.—Mr. Andrew Fullerton presented a report of a group of cases having hematuria as their common symptom. The series included urethral papilloma, enlarged prostate, vesical calculus, new growths, ulceration, varices, and traumatic lesions of the bladder; bilharzia hæmatobia; renal calculus; nephritis; malignant tumor, cystic disease, and tuberculosis of the kidneys; nephroptosis; and injury to the kidney.

Treatment of Fractures by Mobilization and Massage.—Dr. Just Lucas-Championnière of Paris, in this paper, maintained the following thesis, viz.: "Absolute fixation of the fragments is not the most favorable condition for the phenomena necessary to repair at the site of fracture. A certain amount of movement is the necessary condition." Painless massage, followed by passive movements, and as soon as possible by active movements, should be the routine practice. Very rarely deviation of the axis would require correction under chloroform, and the infrequent use of fixed apparatus for a short time. The value of early mobilization was most marked in articular fractures, especially at the shoulders, elbow, and wrist. Fractures of the leg needed discrimination as to treatment—some must be immobilized, and an exceptional case might demand suture.

Spasmodic Torticollis.—Mr. Robert Kennedy presented this communication. The treatment advocated for the severe form of this affection was section of the posterior primary divisions of the upper cervical nerves, which were best reached through an incision along the outer edge of the complexus muscle. Drawings illustrating the anatomy of the region concerned were exhibited.

Technique of Tarsectomy for Talipes Equinovarus.—By Dr. Charles Willens of Ghent. An operation, called "anatomical" tarsectomy, in distinction from "cuneiform" tarsectomy, was described. It consisted of four steps: (1) Excision of a piece of skin over the extensor brevis digitorum; (2) entire removal of the astragalus; (3) resection of the anterior third or more of the calcaneum, and (4) rotation of the foot so as to approximate the cuboid to the tibiofibular surface of the ankle joint. It was claimed that excellent functional results followed, and that tarsectomy was superior to bloodless orthopedic treatment, and to Phelps' operation. In the discussion Dr. Starr of Toronto objected to Dr. Willens' excision for juvenile clubfoot. He preferred removal of the head of the astragalus, combined with a wedge of bone from the calcaneum.

Mr. Cuthbert and Dr. Lucas-Championnière supported Dr. Willens' opinion in favor of tarsectomy as against manipulations.

Some Points About Puncture of the Brain.—Prof. Tillmanns of Leipzig read this paper. The technique of the operation was described. When drainage is indicated for the relief of hydrocephalus, the author would resect the lateral ventricle from above, rather than from the front or side of the skull.

Selection of the Method of Operating for Cancer of the Rectum.—By Mr. Douglas Drew. The combined abdominoperineal method was recommended on the ground that hemorrhage could thereby be more readily controlled, and the growth more thoroughly examined and satisfactorily dealt with.

Prostatectomy by the Combined Routes.—By Mr. Lynn Thomas. The prostate having been separated by the finger through a suprapubic cystectomy wound, a pair of forceps was passed from the prostatic bag to the perineum, and the latter opened to allow passage of the forceps. A rubber tube, five-eighths of an inch in diameter, was then passed through the perineal wound from above and left in for eight days.

Mr. Sinclair White said that he formerly practised this procedure, but now saw no necessity for a perineal opening.

Surgical Statistics.—By Mr. Ernest H. Groves. The discrepancy observed in statistical tables from various sources was remarked upon, and it was suggested that the surgical registrars of hospitals should cooperate in drafting a scheme to insure more uniform and reliable figures, especially in regard to the percentage mortality of hazardous operations.

Gastrostomy.—Mr. Wilmott Evans, in this paper, urged that the operation, when performed for the relief of esophageal cancer, should not be deferred until the patient was asthenic owing to malnutrition. He advocated Senn's method of inverting a cone of the gastric wall, one and one-half to three inches in length, omitting the detail of making a cuff of omentum. The procedure could be done in fifteen minutes, and leakage never occurred.

The Indirect Treatment of Diseases of the Testis Causing Hydrocele.—Mr. Edred Corner read this paper. It was submitted that in certain forms of testicular disease benefit would accrue from resection of the spermatic vessels, or of the vas deferens.

SECTION OF TROPICAL DISEASES.

Thursday, July 30—Second Day.

Sanitation in Reference to Ankylostomiasis in the Tropics.—Sir Patrick Manson, K.C.M.G., opened this discussion. He said the epidemiologist, the clinician, the pathologist, and the helminthologist had together completed the picture of ankylostomiasis, they had indicated its vast geographical range, the gravity and amount of injury, personal and economic, which it inflicted, had demonstrated its cause and the precise way in which this cause entered and affected the human body, and yet with all that knowledge at his disposal the sanitarian had hardly attempted in tropical countries at all events to seriously grapple with the subject or to avail himself of the splendid opportunity

of conferring an immense boon on tropical humanity. One would have thought that, considering the vast extent and importance of her possessions there, Great Britain would have been the first to grapple with the ankylostomiasis problem as it presented itself in the tropics. Not so, and it was indeed little to her credit that the youngest of colonizing powers, the United States of America, had been first in the field and by her efforts in Porto Rico, Havana, and Panama, had set them an example and shown what could be done by intelligent and energetic tropical sanitation. Ankylostomiasis occurred in all tropical and most subtropical countries; in some rural districts 50 to 90 per cent. of the inhabitants were infected. It was one of the deadliest scourges, and some writers regarded it in the aggregate a more serious disease than even cholera or yellow fever. Surely it was a matter of primary importance that if at all feasible the problem of a special and appropriate sanitation be faced, and this all the more seeing that they had complete assurance that if adequate sanitary measures were applied intelligently and with vigor complete success would follow. The life-history of the cause, namely of the worm, was adequate basis on which to found such sanitary measures, and that life-history they now know. They might attain success by expelling the mature worm or by preventing the hatching out of the egg, or by killing the larvæ, or by preventing contact by the larva with the skin, or they might succeed by combination of two or more of these methods. Could the entire population of an infected area be thoroughly dosed with beta naphthol or with thymol he had no doubt the local ankylostomiasis would be effectually dealt with for the time being; but any such attempt to eradicate anxylostomiasis was bound to fail. It would be vastly beneficial as regards the individuals treated, but not radical as regards the community, because the drugging could not be efficiently carried out and fresh infection would constantly be introduced from without. The compulsory use of shoes or the tarring of the feet to avoid contact with contaminated soil were relatively expensive measures, and certainly would never be employed in the case of native children. In common with many others he regarded fecal disposal as the crux of the ankylostomiasis problems. It was quite feasible, in his opinion, to get the coolie or native to drop his excrements into a hole in the ground and without contaminating the surrounding soil. The eggs, in absence of oxygen, would not hatch, or, if hatched out, the larvæ would have no opportunity of getting at the human skin. That method would cost nothing, and if uniformly and properly and permanently carried out would be absolutely effective. In tropical countries treatment of feces by chemicals or desiccation was out of the question if only on the score of expense. Under ordinary conditions of native life the only practicable method of effectively dealing with ankylostomiasis as an endemic disease must be based on the disposal of the feces. He thought other measures had better not be pressed, so that all available funds and energy should be directed to carrying out the least expensive, least irritating, and most efficient, viz., fecal disposal. Simple though that measure might appear to be, its application was by no means easy. In European-owned or large native plantations or factories the matter should be easy enough. In that case government had merely to decree that latrines of a particular type must be used, and to enforce their use by fine if necessary. But it was otherwise with native villages and scattered communities. To get at these he would suggest that the responsibility for the observance of a latrine ordinance be fixed on some local notable or head man selected by each village, community, or district; that he be made responsible to the medical officer of the district, who in turn would be responsible to the surgeon general of the colony, and that an inspector general be appointed for each group of colonies and be responsible to the Secretary of State for the effective carrying out of ankylostomiasis prophylaxis. As a subsidiary measure he would suggest making use of local post offices for the sale at cost price of anthelmintics just as had been done so successfully in India in connection with quinine. The scattering broadcast of leaflets or posters explaining in simple language the symptoms, nature, treatment, and prophylaxis of ankylostomiasis, and, above all, the teaching in schools would be of much value. Should these measures prove successful, more attention might thus be given to prevention of the introduction of ankylostomiasis by coolie ships and otherwise. The matter of ankylostomiasis was a serious one for the tropics and should be faced.

Ankylostomiasis in British Guiana.—Dr. W. F. Law of British Guiana read this paper. He said ankylostomiasis was a serious disease in British Guiana. The great bulk of their labor supply, especially on sugar estates, consisted of East Indians brought to the country under indenture. The infection was being regularly conveyed from India by newly arrived immigrants. Roughly speaking, some 45 per cent. of them were infected. There was no definite proof that the disease existed in the colony prior to immigration. Now it was widely distributed and affected to a very serious degree the health of the laboring population. Early recognition of the disease was of the highest importance, because unless the patient were treated early he would pass gradually into a state of chronic invalidism and ultimately die from the direct or indirect effects of the disease. With regard to treatment, beta-naphthol was now used more than thymol. It was quite as efficacious, was not followed by any unpleasant effects, and the patients took it much more readily. The eucalyptus and chloroform treatment had been tried but had on several occasions been followed by unpleasant effects, whilst its anthelmintic properties had not appeared to be equal to those of thymol or beta-naphthol. The question of prevention might be summed up in one word, "latrines." It mattered not whether they held that infection took place through the mouth or through the skin, once they had the soil polluted by infected stools the spread of the disease was certain. It had been a struggle of years to get employers of labor to recognize the need for latrine accommodation; when he first advocated it he was met by the objection that the coolie would never use them, but experiment had proved that that was not the case.

Ankylostomiasis in South Africa.—Dr. G. A. Turner of the Transvaal read this paper. He gave a detailed and interesting account of the geographical distribution of ankylostomiasis amongst the natives of South Africa based on microscopical examination of feces and on post mortems. The disease was absent from all the temperate parts; that is to say, Cape Colony (excepting of course De Beers mine), Orange River Colony, Basutoland, Bechuanaland, and most of the Transvaal. Gold miners on the Rand, both European and colored, were not being infected there or at any rate only to a very trivial extent, notwithstanding that infection was pouring down the mines daily and hourly. Probably this was due to several factors: (1) acid (sulphuric acid) reaction of mine waters; (2) iron salts (sulphates) contained in mine waters; (3) low temperature of some mines; (4) dryness of some workings. One mine was an exception to the general rule. In this mine every European employed who went below ground contracted the characteristic cutaneous eruption (bunches) and was found afterwards to harbor the parasite. This mine was a deep one, the temperature below ground high, the mine wet, and samples of mine water gave alkaline reaction. The disease had every opportunity of developing.

Dr. A. May, Government Bacteriologist of the Transvaal, continued the discussion with a "Preliminary report on the inhibitory action of dilute solution of acid on the development of the ova of the *Ankylostoma duodenale*." His experiments showed that dilution of sulphuric acid up to the strength of 0.07 per cent. did not prevent the development of the ova into larvæ, but prevented further growth. Dilutions of 0.25 to 1 per cent. of acid seemed to prevent the development of the ova.

Dr. L. Nattan-Larrier of Paris made some remarks on the treatment of ankylostomiasis by thymol and filices.

Dr. Louis W. Sambon said ankylostomiasis, like malaria, beriberi, and pellagra, was principally a disease of the laboring masses. Its wide range and extreme prevalence, its great potency as a cause of disablement, degeneration, and death, placed it among the most formidable disease scourges of mankind. Yet it is a preventable disease, and to all appearances an easily preventable disease. Its unabated continuance was therefore a crying shame to science, government, and humanity. Sir Patrick Manson had told them how the people of the American Union were now grappling with the disease. Great Britain ought to have been in the field long ago. Now, the least they could do was to cooperate with the Americans by cleansing their own colonies, lest inaction on their part be a serious obstacle to others. The prompt, thorough and successful measures adopted by the Americans against yellow fever and against many other tropical diseases both of man and cattle had proved them to be eminently practical and in the exploitation of knowledge far in advance of any other nation. To cite an example of their own supineness, he need but mention the discovery made thirty years ago that mosquitos foster and convey *Filaria bancrofti*. What had been done in all those years to diminish the incidence of filariasis and its attendant horror, elephantiasis? Nothing —absolutely nothing. The disease would eventually disappear not for any measure taken against it, but because mosquitos were now being exterminated as agents in the spread of malaria and yellow fever. Instead of bestirring themselves to put into act and fact the knowledge that had been acquired more at the cost of professional devotion and life than public money, they found their salaried scientists and officials spending all their energy in a negative direction. The former endeavoring to disprove the best established facts, the latter raising every possible opposition against the most useful measures. With regard to ankylostomiasis modern science had only recently apprehended its cause and was only just beginning to consider what steps might be taken for its eradication, but so long ago as 1550 years B.C. the ancient Egyptians appeared to have had a correct knowledge of its etiology and to have adopted measures for its treatment and prophylaxis. According to Schenthaner and Joachim, the famous Papyrus Ebers rightly ascribed the *aaa* disease or endemic anemia to an intestinal parasite, the *Heltu* worm, for which a remedy was prescribed, and von Oefele had pointed out that the ancient Egyptians associated the disease with the carrying and handling of sand. Might not their extraordinary veneration for the dung-beetle, the *Ateuchus sacer* of modern entomologists, be connected with the prophylaxis of ankylostomiasis and other infections spread by the means of contaminated feces? He made the suggestion merely as a matter of archæological curiosity. They all knew what an important part the scarab played in the theogony of the banks of the Nile. This remarkable beetle was represented on all the monuments of the Pharaohs from the great Delta to the very heart of Nubia; it was carved of all dimensions and in every possible material more frequently than any other figure and from the remotest period. Evidently the ancient Egyptians, perfectly cognizant of the benefit derived from this wonderful scavenger, looked upon it as a tutelary god. This suggestion seemed to him more plausible than any of the fanciful reasons hitherto advanced to explain why they considered the dung-beetle as sacred. In support was the fact that other animals likewise had been consecrated by the Egyptians in order to protect and preserve them on account of the beneficial actions they exercised in keeping down vermin. He need but mention the cat, the kestrel, the viper, natural enemies of the plague-conveying rat. In 1900, in the Roman Campagna, he had had the opportunity of studying the habits of the sacred dung-beetle, and he had been struck by the rapidity with which excreta scarcely dropped were cut up, formed into pellets, and buried deeply in the soil. It would be impossible to find a more perfect method of fecal disposal. With Stiles and Manson he was thoroughly convinced that the proper disposal of the feces was by far the most important measure for the prevention of ankylostomiasis. All other measures would be useless if the infective excrements continued to be scattered over the soil, and they would be unnecessary if the same were properly disposed of. He must say at once, however, that that statement was based on the belief that the endemic anemia of man was caused by a worm incapable of affecting any other host, and that this knowledge of the life-history of that parasite was now correct and complete. Unfortunately, those premises were disputable. In the first place, the endemic anemia of man was not everywhere due to one and the same parasite. They already knew that besides the *Ankylostoma duodenale* discovered by Dubini in Italy in 1838, they had to consider *Nicator americanus*, discovered by Stiles in the United States, in 1902; and *Triodontophorus diminutus*, described by Raillet and Henry in 1905 from specimens in the Paris Natural History Museum, collected forty years previously by Dr. Monestier of the French imperial Navy at the *post mortem* of a negro who had died of endemic anemia in Mayotte. Possibly other forms would be found. Those already known belonged to different genera and two of them were known to have a world-wide distribution. Secondly, it was not definitely proved that those parasites belonged to man exclusively and that allied forms in the lower animals were specifically distinct. Indeed, the forms found in certain ages appeared to be identical with those of man, and Schaudin's experiments had proved that *Ankylostoma duodenale* can develop perfectly well in monkeys. Moreover, other species, such as *A. caninum*, might be found in a number of different hosts. Thirdly, there were many points in the life-history of these parasites which were still obscure. They did not know the relative importance of mouth and skin infection. When introduced by the mouth, did the larvæ invariably pass straight down to the intestine? Might they not penetrate the walls of the esophagus? They were rarely found in the stomach and duodenum. When found in the stomach they were lodged beneath the epithelium. They had been formed in the walls of the esophagus. When large quantities were experimentally fed to dogs they were instantly vomited. We know that they might appear in the jejunum and upper part of the ileum as soon as 42 hours after penetrating the skin, but we did not know how long they might tarry over their migrations. They had been found in the lymph glands and other organs at a stage of growth which, as a rule, they only attained after reaching the intestine. According to Looss, the parasites after penetrating the skin usually through the hair follicles, forced themselves into the lymph vessels, then into the cutaneous veins and, carried by the blood stream, reached the right heart, then the lung. Here they passed from the vessels to the air cells, and finally, creeping up the bronchial tubes and the trachea, they crossed over the larynx and slid down the esophagus to the stomach and then to the small intestine. Of course Looss had thoroughly demonstrated in the case of ankylostomiasis the truth of the old popular belief that certain parasitic worms might enter the economy by way of the skin and his experiments with *Ankylostoma duodenale* and *A. caninum* had been confirmed by numerous and able investigators not only with these worms, but also with *Nicator americanus* and *Strongyloides stercoralis*. He was also perfectly aware that, as pointed out by Looss, the larvæ of *Ankylostoma duodenale* reached the lungs and might be found in considerable numbers either in the walls of the air passages or within their lumen. But Rainey had proved it half a century before, although mistaking the parasite for a filaria which he had proposed to call *Filaria trachealis*. But as he (Sambon) had stated elsewhere, he doubted the correctness of the last part of

the journey from trachea to jejunum as traced by Looss *via* larynx-esophagus-stomach-duodenum, or at any rate he did not believe it could be the usual route. He (Sambon) believed that the majority of larvæ penetrated the lumen of the jejunum and upper part of the ileum through the wall of the bowel. In evidence he would point to the absence of parasites in the duodenum, to the intense hemorrhagic inflammation of the jejunum at the beginning of the infection which entirely subsided later on notwithstanding the presence of enormous numbers of parasites in the intestine, and to the actual presence of miniature worms in blood-filled spaces beneath the intestinal mucosa, observed again and again by Bilharz, Griesinger, Sonsino, Grassi, and others. Finally he thought analogy with the life-history of other intestinal parasites supported this mode of entrance. Then, again, they did not know how long the adult worm might live within the intestine. Some said weeks, others months, others years. They knew for certain that the females matured and began to oviposit about four weeks after penetrating the skin. The process of egg laying might continue for a considerable time, but it was unlikely that the longevity of the parasite might explain infections of eight, fifteen, or twenty years' duration. It would be important to ascertain the exact rôle played by reinfection in such cases. With regard to the anemia, we were still uncertain whether to ascribe it to blood abstraction, to venom secreted by the head glands of the parasite, or to secondary infection. The blood-abstraction theory had been considerably shaken of late, since it had been practically demonstrated that the parasite was not a true blood-sucker. The toxin theory had more partisans than facts in its favor, the microbic theory seemed more in accordance with recent investigations. Certainly many individuals harbored the worm without showing any signs of obvious illness, and perfect health did not appear to be inconsistent with the presence of hundreds of parasites. Boycott stated that in the Cornish mines, after examination of about a quarter of the underground hands taken at random, he had failed to obtain satisfactory evidence that a single man was without the worm. Yet at the worst, not more than 10 per cent. of the men were actually ill, and the great majority expressed themselves to be in perfect health. These and many other questions in the life-history of the parasite were of the highest importance with regard to the prophylaxis and treatment of the infection and should be thoroughly worked out, because the more complete their knowledge of the bionomics of the parasite the better their chances of efficient prophylaxis and treatment. In the present state of their knowledge, which was no doubt perfectly correct in the main lines, they could safely state that the prophylaxis of ankylostomiasis lay entirely in the proper disposal of the infected excreta. Besides, any measure taken against fecal contamination of the soil would be amply repaid because it would not only tend to stamp out ankylostomiasis, but also many other diseases due to bacteria, to protozoa, or to metazoan parasites which left the body by way of the intestine. And he would again point out, as he had done at a previous meeting of that section, in 1903, that whatever be the method employed, human feces should never be used for agricultural purposes because they were far too dangerous, especially when used for the manuring of salads and vegetables that were eaten raw. It would be a great mistake to rely on fermentative processes or even chemical disinfection to render contaminated feces innocuous. The powers of resistance shown by the spores of certain bacteria, the marked stages of certain protozoa, and the ova of certain worms were almost incredible. If they could not be destroyed in the laboratory how could we expect to destroy them in nature? He believed it would not be a matter of impossibility, by persuasion, education, example, and judicious coercion, to teach the natives of their colonies more hygienic habits with regard to the disposal of their excreta. The cat invariably buried its excrements with the greatest care, this habit had been ascribed to the necessity for the animal of concealing his whereabouts, but that explanation seemed absurd when they considered that the cat had no predatory enemies. Besides, in many other animals we found the habit of depositing their excreta at a distance from their burrows and nests for no other purpose than strict hygiene. Surely it should not be impossible to evolve such an instinct in man. In conclusion he hoped that Sir Patrick Manson's warning and suggestions would reach the appropriate quarters, strengthened by their unanimous approval.

Dr. C. W. Daniels of London stated that he did not think sufficient importance had been attached to the destructive action of certain dipterous larvæ, particularly those of the sarcophagidæ which lived in the feces till nearly mature and destroyed all thin-shelled entozoal eggs. He was not in favor of compulsion by government, and thought that more could be done by quiet action on the part of the medical authorities than by active government action which might defeat its own ends.

Dr. F. M. Sandwith of London said he used to be an ardent exponent of the virtues of thymol, but the severe effects produced in some patients had caused him now for some years to prefer beta-naphthol or the combination of eucalyptol, chloroform, and castor oil. The important question of prophylaxis could be most easily and most cheaply met by preaching the doctrine of early burial of feces in dry earth or sand. The eggs could not develop without moisture. Ankylostomiasis as an endemic disease should be treated as regards fecal disposal as they had learned to treat epidemics of cholera and enteric fever.

Sir R. Havelock Charles said Dr. Sambon had referred to the sanitary work of the ancient Egyptians; he might also have referred to the better-known sanitary laws of Moses. What did the Hebrew do when going to the field in the early morning? He had a "paddle upon his weapon" and making a hole he buried and covered up his deposit therein. Thus were destroyed myriads of ankylostomes. The crux of the whole question, as Sir Patrick Manson had said, was fecal disposal. He believed in education. Get at the children, and in a generation you will have the adults.

Sir Patrick Manson, in reply, said he was glad to gather from what had been said that the section was quite in sympathy with his remarks on the desirability for an effort being made to mitigate the plague of ankylostomiasis in the tropics, and further, that the method of attack should be directed towards fecal sanitation. He was disappointed with the pessimistic attitude assumed by Dr. Daniels towards the suggestion that government should move in the matter. If government did not move, nothing would be done. One might say truly that it was everybody's duty to move in the matter, but it was well known that everybody's duty was no one's work. Government interference should be wise interference; it need not be irksome, but government certainly should set the ball a rolling. In the West Indies which were ravaged by ankylostomiasis no one was moving except the United States Government.

The Diagnosis of Latent Malaria.—Dr. A. Plehn of Berlin read this paper. He said three phases might be distinguished in latent malaria. A first phase, which might be termed "primary period of latency," lasting from the moment of infection to the first paroxysm of fever. A second phase, covering the successive periods intervening between the single fever of paroxysms, which he proposed to call "intermediate period of latency," and a third phase, the "final period of latency," which followed the last recurrence of fever and did not usually last over six months. The first phase was characterized by nervous excitability, dyspepsia, and more or less severe anemia. The erythrocytes showed basophilic granules. At one time these symptoms were looked upon as evidence of acclimatization, but they were unknown in the healthy parts of the tropics. In the second phase, during the periods intervening between the pyrexial attacks there might be no

clinical symptoms or only slight anemia, but sometimes the approaching paroxysm might be preceded by symptoms similar to those of the first phase. Immediately before the fever attack, malarial parasites might be found in the blood; after it, particles of pigment in the leucocytes, especially in the large mononuclears, and later gametes until about three weeks after the attack, seldom as long as six weeks. Basophilic granules in the erythrocytes were always present during all periods of latency, but soon disappeared in patients who returned to Europe even before the extinction of the malarial infection, as proved by subsequent pyrexial attacks. The continuance of latent infection was also evidenced by the relative increase of the large mononuclears which might reach a percentage of 15 to 20 or more of the entire number of leucocytes. But the leucocyte rate was not a reliable sign since it returned to normal, notwithstanding the continuance of the infection, and was also found in other protozoal diseases (trypanomiasis spirochætiasis). The last phase seldom lasted over six months; its symptoms were identical with those of the preceding one. The recognition of this last phase was of importance because the cessation or continuance of quinine treatment depended entirely on it. He would therefore like to draw their attention to a symptom easily recognizable which might indicate the presence of latent malaria when all other signs were wanting. That symptom was urobilinuria. Of course urobilinuria was not a specific sign of malaria like the presence of gametes in the blood. It was merely a symptom of liver disturbance from which, however, the continuance of malarial infection might be concluded with great certainty in the absence of any other cause which might explain the liver affection. On the other hand, urobilinuria might not be found in every case of malarial fever, because in exceptional cases malaria might spare the liver. But the presence of marked urobilinuria after malarial fever certainly proved that the infection was not entirely spent. In conclusion, he hoped that his remarks might promote further investigations. The question of the recognition of latent malaria in its different stages was one of great importance and, considering the uncertain nature of its symptoms, any new sign would be of value.

Dysenteric Amebæ and Liver Disease.—Dr. E. Marchoux of Paris read this paper. He said that in 1899, in Senegal, he had made some investigations on amebic dysentery and shown that, as previously discovered by Kartulis, it was easy to transmit the disease to cats by means of amebæ-containing stools. He had infected 82 cats by means of serial passages; 52 of these cats died of liver abscess. The abscesses varied in number from 1 to 7 and in size from the dimensions of a pea to those of an egg. All developed in from 12 to 18 or more days and contained living amebæ. They also contained some bacteria: 23 times staphylococci, 17 times various anaërobes, 6 times bacilli of the coli group, 4 times streptococci, twice proteus vulgaris. At the same time he had had the opportunity of examining the pus of 27 abscesses in human livers, and only twice he had found the pus sterile by the cultural method. Thirteen times he had found staphylococci, 6 times undetermined anaërobes, 4 times bacilli of the coli group, twice streptococci. In 17 of these cases there were amebæ. In three cases in which no amebæ were found in the liver, they were discovered in the stools. The 25 cases of abscess which had given bacterial cultures were of relatively recent origin. No less than 24 had been operated in the country in which dysentery had been contracted. All the patients had presented a high temperature. Of the two abscesses infected with streptococci, one had been discovered at the autopsy, the other in a patient with very high temperature who died from streptococcic septicemia on the day following operation. One of the two abscesses with sterile pus had been operated one year after the appearance of signs of acute hepatitis, the other two years after recovering from dysentery. These facts led to conclusions identical with those given by Kartulis in his report of 1903: (1) The liver abscess always contained some bacteria at the outset. (2) Later it became aseptic in the same way as old abscesses after the death of the microorganisms which gave rise to them. The dysenteric amebæ were always hematophagic, but this was in all probability an acquired character, and not one sanctioning the placing of all such as exhibited it in one single species. An ordinary ameba after having lived in the intestine as a commensal might some day for one reason or another begin to feed on red blood corpuscles. From that moment it became pathogenic—attracted by the new food, it would penetrate the walls of the bowel and go in search of it. But it did not follow that it would adopt it exclusively. Even those best adapted to a parasitic mode of life continued to engulf bacteria. Those he had studied in Senegal, and which so rapidly produced abscess of the liver both in man and cats, engulfed not only erythocytes and bacteria, but even took up carmin granules which he had purposely added to the preparation. Considering that they came from the intestine, it was no matter of surprise that they should carry bacterial infection wherever they went. Dophr had pointed out that amebæ had the power of producing necrosis at a distance, and in further proof of the bacterial infection of liver abscesses he would remind them of the leucocytic formula of the blood in such cases. Rogers and Lézer had shown that it was characterized by an abundance of polymorphonuclears. Rogers had seen at times the proportion of polymorphonuclears rise to 90 per cent. of leucocytes. Protozoal diseases always brought about a mononuclear increase, they must therefore admit that the larger proportion of polymorphonuclears in patients suffering from liver abscess was due, not to the amebæ, but to the associated bacteria. When the bacterium which reached the liver abscess was highly pathogenic it conferred to that affection a character of extreme gravity. The two cases already mentioned in which streptococci were found proved it conclusively. Finally, one more fact deserved attention. Almost invariably in liver abscess they found a pure culture of a single species of bacterium. In only three cases infested with anäerobes he had found simultaneously several species of bacteria. Such purity was surprising at first sight. No doubt it was the outcome of struggle, one species surviving out of the several probably present at the start.

Sir Patrick Manson said it was a matter of gratification to the section of tropical diseases that men of the high standing of Dr. Plehn and Dr. Marchoux thought it worth their while to be present there and to take part in their work. Both of them had served a long apprenticeship in tropical pathology and had attained positions of special distinction in that department of medicine. The importance of recognizing latent malaria was especially great in regard to Great Britain and her tropical possessions. Any method that would enable them to recognize when a man was the subject of latent malaria or when he was free from infection would be a welcome addition to practical medicine. The presence of basophilic granules in the erythocytes was an unreliable test, for they occurred in many other infections, notably trypanosomiasis. The possible duration of a malarial infection had not been definitely ascertained. Personally, he had never seen a case of malaria, that is, a malaria diagnosed by the microscope, last longer than three years. With regard to the administration of quinine his own practice was to advise those who had been in the habit of taking prophylactic quinine in malarial countries to continue the use of the drug for at least three months after their return to England, and intermittingly for a further period of one to two years. He had seen disregard of this practice culminate in fatal attacks of blackwater fever.

Dr. Malcolm Watson read a few remarks on rare nervous symptoms seen in malarial patients.

Blackwater Fever.—Dr. Louis W. Sambon said blackwater fever had been mentioned both by Dr. Plehn and Sir Patrick Manson in conjunction with malaria, and he seized the opportunity to again state most emphatically that blackwater fever was a disease entirely distinct from any of the known forms of malaria. Many years had passed since he first pointed out that blackwater fever was a specific disease more closely allied to the bacterial infections of the lower animals and to yellow fever than to malaria. Now he was more than ever convinced of the correctness of his hypothesis because, although he had had no opportunity of examining patients or making post mortems, he had been able to gather some interesting information tending to show that the disease was a tick-borne disease.

Forms of Ankylostoma in Australia.—Dr. Robert T. Leiper, helminthologist to the London School of Tropical Medicine, stated that a private letter addressed to Dr. Sandwith from Dr. T. L. Bancroft of North Queensland had been handed in that morning to the section of tropical diseases. It said that quite recently in some notes on tropical diseases B. A. O'Brien, M.D., had advanced the opinion that the parasite which caused endemic anemia in Queensland was not the *Ankylostoma duodenale*. Dr. Bancroft had forwarded a supply of worms from an anemic boy for diagnosis. Dr. Sandwitth and himself had just examined them and they had found them both *Ankylostoma duodenale* and *Nicator americanus*. None of the specimens appeared atypical. This record of the presence of both known forms in Australia was highly interesting. It rounded off their information of the geographical distinction of the "American" form, the presence of which he had personally determined (1) throughout tropical Africa in Gold Coast, Congo, Uganda, Mombasa, Mozambique, Nyassaland, British Central Africa; (2) India, from Ceylon, Mysore, Assam, and (3) in China. Its occurrence in Australia demonstrated finally its worldwide distribution. Dr. O'Brien's paper was the second published within the current year hinting at the occurrence of a distinct Australian species, but no facts had been advanced in support of that contention.

Friday, July 31—Third Day.

Lymphatic Diseases in the Tropics.—Dr. C. W. Daniels, director of the London School of Tropical Medicine, opened this discussion. He said that in practically all tropical diseases some implication of the lymphatic system did or might occur whether the disease were due to bacteria, protozoa, or metazoan parasites. In many the lymphatic condition was only of diagnostic value, as it led to little or no direct ill effect. In many of the protozoal diseases enlargement of the glands might be met with. In malaria it was exceptional, but did occur. In other protozoal diseases, and especially in those caused by flagellates, including Leishman-Donovan bodies, enlargement of the glands was constant, and the parasites were found in large numbers in the lymphatic glands. In trypanosomiasis they were of great diagnostic value as superficial glands, especially those of the neck, were early involved, and not only could the enlarged glands be readily felt, but trypanosomes were more readily found on gland puncture than in the peripheral blood. Cutaneous breaches of continuity from biting arthropoda, ticks, flies, mosquitos, and the like, and in some places from leeches, were so frequent that naturally lymphangitis and adenitis were more common than in England, and were reported more often. It was therefore of interest to notice that these frequent recurring attacks of lymphangitis were not ordinarily attended by any general lymphatic obstruction. The same might be said of the more chronic ulceration, with the exception of that due to the granuloma of the pudenda. In the latter disease the glands were not obviously enlarged, no secondary deposit took place, and yet chronic lymphatic obstruction, resulting in swelling resembling the ordinary tropical elephantiasis, occurred in penis, scrotum, and vulva. These rarely attained any great size, but were quite noticeable. The lymphatic bacterial disease most definitely associated with the tropics was the plague bubo. In that disease lymphangitis was little marked, the whole stress leading to absolute destruction of the glands was the marked feature. Closely resembling in clinical aspects the rare ambulant cases of bubonic plague were the so-called climatic buboes. In these also there was no evidence of lymphangitis, but the glands were enlarged and tender, with some febrile disturbance. They did not contain any plague bacilli. In the cases he had seen there had been definite suppuration. The lymphatic diseases which were more especially associated with tropical conditions were those due to metozoan parasites. In many of them the eggs were deposited amongst other places in the glands, and might, as in *Schistosomum japonicum*, be very numerous. In such cases the glands were enlarged and fibrotic, but there again no obstructive symptoms occurred. In most tropical countries elephantiasis was common, and other evidences of lymphatic obstruction, such as chyluria, were also fairly common. Much speculation as to the causation of this condition had taken place. Lymphatic obstruction was not confined to the tropics. Rare cases occurred in England, and were indistinguishable from tropical elephantiasis. Personally he had seen two cases. The problem, therefore, was why lymphatic obstruction sufficient to cause chronic edema, a rare disease in England, in the tropics might affect 5, 10, 15 per cent. of the population. They knew it might occur from several causes, but why should it be so common in the tropics unless a special cause existed? The discovery of *Filaria bancrofti* in the lymphatics naturally suggested a plausible hypothesis to account for this difference in frequency. Filariæ were common in the tropics and unknown in temperate climates, as elephantiasis was or nearly so. In most cases of elephantiasis no filaria embryos were to be found. Indeed, it was the people who gave no direct evidence of filariasis who had lymphatic obstruction. This seemed at first sight contrary to any relationship between filariasis and elephantiasis, but the connection was indicated by identity of geographical, topographical, racial, and sex distribution, as well as by the distribution of known intermediate hosts. Thornil in Ceylon had shown that in natives of Colombo filariasis and elephantiasis were rare, compared with certain places a few miles out. Low in the West Indies had shown that a definite ratio held good. In British Central Africa the relationship was very definite; in large tracts of the country there was no elephantiasis and no filariasis. In the Shire Highlands filariæ were only found in immigrants. The same applied to elephantiasis. On the lower Shire river filariasis was more common and elephantiasis occurred higher up the river. Higher up the river neither were found. At the southern end of Lake Nyassa he had found no elephantiasis, only one person with filaria, and scanty mosquitos capable of transmitting the infection, whilst at the northern end he had observed fairly numerous cases of filaria, several cases of elephantiasis, and an abundance of suitable mosquitos. Observations of that kind could be multiplied indefinitely. In every case careful examination had confirmed the relationship. The old objection that cases of lymphatic obstruction were the cases in which fewer people harbored filarial embryos than the average population need not detain them. All it meant was that in lymphatic obstruction the embryos were not able to enter the circulation. How did the filaria lead to lymphatic obstruction? In the first place, it caused thickening, dilatation, and other changes in the wall of the channel. Occasionally it gave rise to hemorrhage. He had himself seen dilated masses of lymphatics containing living filariæ distended with recently coagulated blood. Again, suppuration with abscess formation occurred, either as a result of the death of the worm or in some way connected with its presence, and in the contents of such abscesses remains of the worms

had been found. Elephantiasis might occur as a direct sequence of a single attack of acute inflammation, or after repeated attacks of a similar nature, or gradually, without pain or any erysipelatoid attack. He did not think it necessary that all cases of elephantiasis need be assumed to be produced in the same manner by the filaria. In some it might be hemorrhage; in others, perhaps more common, it was merely that the lymphatics distended and altered by the filariæ were more liable to inflammation. The acute lymphangitis was probably due to the introduction of bacteria. Manson believed that the adult worms under certain conditions aborting were the real cause of some cases of obstruction. The aborted embryos, instead of being fully obstructed as when normally discharged, were still coiled up in their egg capsules, which, according to the stage of development, might be round or elliptical. Their shorter diameter being larger than the smallest lymphatic channels, the ova were stopped in the glands and blocked up all the anastomosing branches till there was complete obstruction. Manson's hypothesis had not received the full consideration it required. It seemed to have been tacitly condemned as too complicated and involving a whole series of suppositions. On analysis, however, every point in the hypothesis rested on actual observations. It was more than possible, it was a logical sequence that must almost necessarily follow, and gave a complete explanation of the phenomena observed.

Dr. W. Prout, C.M.G., of Liverpool said that in Europeans one occasionally found a bubo which was called "malarial" or "climatic." As to the former, he had seen no evidence. As to the latter, there was undoubtedly a form of suppurative lymphadenitis for which there appeared to be no appreciable cause. The name given to this disease was only an expression of ignorance. He contended that facts of geographical distribution were opposed to the theory of relationship between elephantiasis and filariasis. In his opinion elephantiasis was a streptococcal disease.

Sir Patrick Manson was glad Dr. Daniels had given an accurate outline of his views, which were generally misunderstood. He did not say that the hypothesis had been proved. He recognized the propriety of an attitude of doubt towards it, but not of denial. To his way of thinking it was a most probable explanation of the facts.

Dr. Louis W. Sambon said Dr. Daniels had very ably shown that there was much evidence in favor of a relationship between tropical elephantiasis and filariasis. In Europe cases indistinguishable from tropical elephantiasis were occasionally met with. They were looked upon by some as disproving any connection between filariasis and elephantiasis in tropical countries. He was not going to discuss the various causes which might bring about lymphatic obstructions in Europe, but he wished to point out that a filarial predisposing cause was by no means excluded in European cases of elephantiasis. *Filaria bancrofti* had a very wide distribution, and was certainly found on the African and Asiatic coasts of the Mediterranean. Possibly it occurred also on the European side. At any rate its occasional appearance there was more than probable. Indeed, a well authenticated case had been described in 1894 by Dr. M. Font y Torné, in a Spaniard from Canet de Mar (Barcelona) who had never left his country. This man suffered from chyluria and enlargement of the scrotum. His blood contained filaria larvæ. There was no reason why *Filaria bancrofti* should not prosper in certain parts of Europe. They knew that innumerable species of filariæ lived in the mammals, birds, and reptiles of Europe; some also in man, as, for instance, *Filaria labialis, f. conjunctivæ* and other ill-determined species. All these filariæ were fostered and transmitted by arthropod intermediary hosts which might be flies, mosquitos, or ticks, according to the species. *Filaria mimitis*, the "cruel filaria" of dogs, had a very wide distribution in tropical and subtropical countries, but it was found also in northern Europe (France, Germany, Denmark, England). Like *F. bancrofti*, it was propagated by mosquitos.

Dr. J. Maxwell of Formosa pointed out that the island of Formosa was in practically the same latitude as Amoy on the mainland. The inhabitants were for the most part Chinese immigrants from the Amoy region. The customs, habits, and diseases were with one exception exactly the same, that exception being the presence of filariasis and elephantiasis, as a very common disease in the Amoy region, and the almost complete absence in Formosa of both diseases.

Captain J. W. D. Megan, I.M.S., stated the facts he had observed in two districts in Bengal. In Puri, where elephantiasis was common in 100 prisoners whose blood was taken at night and examined, filarial embryos were found in 15. (Three of the prisoners suffered from elephantiasis; in none of these were filarial embryos found.) In Dinajpur, where elephantiasis was rare, in 50 prisoners taken at random the blood taken at night showed *no* filarial embryos. (None of the prisoners in Stin jail (300 in number) suffered from elephantiasis.)

Dr. A. Powell of Bombay said in many Indian birds, owls, kites, etc., filariæ were common in the lymphatic and subcutaneous tissues like *F. bancrofti* in man, but they did not find any elephantiasis, as far as he was aware. He might add a few figures bearing on the relative incidence of filariasis and elephantiasis. In Cachar, where elephantiasis was rare, except when imported, of 256 indigenous persons whose blood he had examined only one showed filariæ. In Bombay, where elephantiasis was not uncommon, of 363 night bloods examined 18, about 5 per cent., showed filariæ. On the other hand, the families of seven cases of elephantiasis, 43 persons, showed no case of filariasis. That filariæ produced inflammation was undoubted. The phenomena of inflammation had been often studied in the cornea of the rabbit. In the swampy districts of India Nature often gave them a beautiful demonstration in the case of filaria in the eye of the horse. He had often watched the course of the disease. A white worm about 1½ inches long was suddenly seen in the anterior chamber of the horse's eye, darting about like a miniature eel in an aquarium. Usually the aqueous and cornea remained clear for about 48 hours, then both became steamy, iritis set in, and in four days' time the cornea was dead white and opaque unless the worm had been removed.

Professor A. Pastellani of Ceylon described a palliative treatment of elephantiasis by means of thiosinamin or fibrolysin injections and methodical bandaging, followed by removal of portions of the redundant skin when most of the fibrous tissue had been absorbed.

Sir R. Havelock Charles disputed Manson's theory of elephantiasis. The anatomical arrangement of the lymphatics as to distribution and valvular mechanism prevented the one from passing from one side of the body to the other and the theory demanded the presence of an aborting female in many and various parts to account for the clinical facts that the disease in the scrotum was usually symmetrical. After complete removal of a scrotal tumor there was no return of the trouble, although the so-called "obstruction" remained. But a recurrence would surely follow if the least amount of unhealthy tissue remained in the penis or perineum. This showed that the disease was in the parts removed, and not in those that were left. He spoke at length of treatment.

Dr. L. Nattan Larrier of Paris described some interesting cases of sleeping sickness with nervous mental symptoms.

Dr. Daniels then replied. With regard to the symmetrical condition of the scrotal affection he said that was common to all conditions where the loose cellular subcutaneous tissues of the scrotum were involved. As to noninfection of other members of families he had observed a similar condition in British Guiana with regard to filariasis. Frequently one member only of a family

was infected. A person with elephantiasis having no embryos in his peripheral blood was not so likely to infect other members of the family as a person with filariæ and without lymphatic obstruction.

Bilharziasis.—Mrs. Bouté Sheldon Elgood, M.B., London, read a paper on bilharziasis among women and girls in Egypt. It showed that the disease was common in young girls, even in those who did not bathe, and who used filtered water only. Town children were frequently affected. Bilharziasis was rare in adult women, who might, however, have suffered from it in youth. European women and girls were not known to suffer from it, though in the towns they drank and washed in water from the same source as natives used. Water, however, was not stored in European households. Infection was probably not due mainly to bathing, as had been suggested. It was possibly due to faulty storage of drinking water or to the eating of raw vegetables and fruit washed in dirty canals or rivers.

Dr. Armand Ruffer said he was of opinion that women in early life were as much infected as men. Infection might be due to ablutions, and was possibly rectal.

Dr. F. M. Sandwith said Dr. Ruffer's suggestion would hardly explain the prevalence of bilharziasis in the English soldiers in South Africa.

Sir Patrick Manson said Mrs. Elgood had made a most important contribution towards the solution of the problem of the etiology of bilharziasis, which for many years had been languishing for want of new facts. He disputed Dr. Ruffer's suggestion of infection per anum.

Dr. Louis W. Sambon moved a vote of thanks for the president for the admirable manner in which he had conducted the business of the section.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Transactions of the American Pediatric Society. Nineteenth Session. Edited by Linnaeus Edford La Fetra, M.D., Volume XIX. 8vo, 220 pages; illustrated; cloth. E. B. Treat & Company, New York.

Lehrbuch der Muskel und Gelenkmechanik. By Dr. H. Straber. 8vo, 212 pages; illustrated; paper. Julius Springer, Berlin.

Grundriss der Allgemeinen Symptomatologie. Von Dr. Med. R. Oestreich. 8vo, 327 pages; paper. August Hirschwald, Berlin.

The Principles and Practice of Hydrotherapy. By Simon Baruch, M.D. 8vo, 544 pages, illustrated. Cloth, $4.00 net. William Wood & Company, New York.

The Sanitation of Recreation Camps and Parks. By Dr. Harvey B. Bashore. 12mo, 109 pages, illustrated. Cloth, $1.00. John Wiley & Sons, New York.

Traitement Chirurgical Actuel des Kystes Hydatiques du Foie et de leurs Complications. Par le Dr. Albert Cauchoix. 8vo, 168 pages. Paper, illustrated, 3 fr. 50. G. Steinheil, Paris.

STATE BOARD EXAMINATION QUESTIONS.

Ohio State Board of Medical Registration and Examination.

June 8, 9, and 10, 1908.

ANATOMY.

1. What is the difference between mucous and serous membranes?
2. What forms the deep palmar arch?
3. Describe the origin, course, and distribution of the renal arteries.
4. Describe the different varieties of epithelium.
5. Name the muscles that form the abdominal walls.
6. Name the cavities, openings, and valves of the heart.
7. What features of the bony skeleton characterize the sex?
8. What is a ginglymus joint? Give an example.
9. Give the gross anatomy of the liver.
10. Describe the cerebellum.

PHYSIOLOGY.

1. What part of the nervous system is involved in stammering speech?
2. Describe the pneumogastric nerve and its function.
3. Where are the red blood corpuscles formed and what is their function?
4. Describe lymph. How is it formed?
5. Into what classes is food divided? Give a general description of each.
6. What is the pulse and what do its varieties signify within physiological limits?
7. What are proteids and how are they formed?
8. What physiological conditions influence the secretion of urine?
9. Describe the physiology of menstruation.
10. Where and in what form do the hydrocarbons reach the circulation?

CHEMISTRY.

1. What is the action of a solution of potassium permanganate when used as a disinfectant?
2. Give a simple test for organic impurities in water.
3. Give the reaction of cow's milk and mother's milk.
4. Name the inorganic constituents of the gastric juice.
5. What is the difference between urea and uric acid?
6. Give the formula, properties, and uses of hydrogen dioxide.
7. What chemical tests are most important in the analysis of urine?
8. Give the chemical names for cream of tartar, Glauber's salt, Epsom salt, copperas, sugar of lead, and common salt.
9. What antidotes should be used in corrosive sublimate poisoning?
10. Name four organic acids and give the source of each.

MATERIA MEDICA AND THERAPEUTICS.

1. From what is senna obtained? Give some indications for its use and the preparations employed.
2. Name three drugs that may be used to increase the flow of urine.
3. Write a prescription for internal use in a case of chronic eczema of the gouty type.
4. What antidote would you use in a recent case of poisoning by opium taken by the mouth?
5. When should alkalies be given with reference to meals? Why?
6. What are some of the therapeutic uses of ammonium carbonate? How should it be exhibited?
7. Upon what does the therapeutic value of calcium depend?
8. What remedy do you suggest to be used in diabetic coma?
9. Name three styptics.
10. What are some therapeutic aims of the hot pack?

PHYSICAL DIAGNOSIS.

1. State diagnostic value of decreased resonance of the percussion sound over the lung.
2. State diagnostic significance of dullness or flatness in the left anterior axillary line from the sixth to the eighth rib (Traube's area).
3. What pathological meaning has an amphoric resonance on the chest elicited by percussion?
4. What pathological significance is attached to the cracked-pot sound?
5. In what affections of the lungs is bronchial breathing found?

6. Explain significance of friction sounds.
7. What pathological significance is derived from the enlargement of the superficial abdominal veins (caput medusæ)?
8. What diagnostic significance is given by a frequent pulse (tachycardia)?
9. State pathological significance of the facial paralysis.
10. Describe location and quality of murmurs indicating mitral insufficiency.

PRACTICE AND PATHOLOGY.

1. What points in the microscopical appearance of sarcoma would enable you to make a diagnosis?
2. Describe the technique of rectal alimentation. What foods are used?
3. What symptoms mark failure of compensation in chronic valvular diseases of the heart?
4. What amount of urine is excreted in twenty-four hours in health? What is its specific gravity? How are each of these influenced in:—Acute nephritis? Chronic parenchymatous nephritis? Chronic interstitial nephritis? Diabetes mellitus?
5. Describe a typical case of typhoid fever from time of infection.
6. Name the exanthemata acuta and give time of eruption of each.
7. What condition does (*a*) a decrease of hydrochloric acid indicate? (*b*) An increase?
8. Describe eczema and give treatment.
9. Give the Diazo-reaction test. What does it diagnose and prognose?
10. Discuss immunity, giving attention to acquired immunity, to toxin immunity, and to the theories of the nature of immunity.

SURGERY.

1. Differentiate shock and hemorrhage, postoperative, as to diagnosis and treatment.
2. Give surgical anatomy of kidney.
3. Give treatment of compound fracture of upper third of femur.
4. Give indications for operative interference in cholelithiasis.
5. Give treatment of cancer of sigmoid flexure of the colon.
6. Describe a method of lateral intestinal anastomosis.
7. What are the blood findings in pyogenic osteomyelitis?
8. Give indications for enucleating eye.
9. Give common sources of wound infection.
10. Describe resection of shoulder joint.

GYNECOLOGY.

1. Describe the structure of the perineal body.
2. Enumerate three causes for suppression of menses.
3. Differentiate pelvic hematocele from pelvic abscess.
4. What may result from lacerated perineum?
5. Describe the technique of washing the urinary bladder and in what conditions it is indicated.

DISEASES OF CHILDREN.

1. Discuss briefly icterus neonatorum.
2. Write a prescription for modification of cow's milk for a child three months old.
3. Give etiology of otitis media.
4. Give etiology of infantile endocarditis.
5. Give diagnosis and differential features of basilar meningitis.

OBSTETRICS.

1. Describe the blastodermic vesicle.
2. Name some of the causes and some dangers incident to protracted labor.
3. Make a diagnosis of syphilis of the newborn; state something concerning the prognosis.
4. What conditions contraindicate the operation of version?
5. What changes in the blood are produced by pregnancy?
6. How is labor usually influenced by a kyphotic pelvis?
7. The presenting part is well engaged in the pelvis; the anterior shoulder is felt to the left but near the median line; the fetal heart sounds are heard about midway on a line from the left anterior superior spine to the umbilicus; what are the probable presentation and position?
8. What measures would you suggest to overcome uterine inertia?
9. How soon should the cord be ligated? Give your reasons.
10. How recognize tetanus neonatorum?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

OHIO STATE BOARD OF MEDICAL REGISTRATION AND EXAMINATION.

June 8, 9, *and* 10, 1908.

ANATOMY.

1. *Mucous membranes* consist of an epithelial surface containing glands, a basement membrane, supporting connective tissue, with blood and nerve supply. They are found lining passages by which the internal parts connect with the exterior of the body.

Serous membranes consist of a single layer of endothelial cells, with no glands, upon a connective tissue membrane, with blood-vessels, nerves, and lymphatics. They form closed sacs lining visceral cavities (with the exception of the peritoneal cavity in the female).

7. The *features of the bony skeleton which characterize sex*, are: (1) In the male the bones are, as a rule, stronger, larger and heavier, and the prominences, ridges, and lines are more distinct; (2) the skull in the male looks more mature, and less like that of a child, and the glabella is more prominent; (3) in the female the sternum is shorter, the capacity of the thorax is less, and the upper ribs are more movable; (4) in the female the clavicle is shorter, thinner, smoother, and less curved; (5) in the female the sacrum is relatively wider, less curved, and is directed more obliquely backwards; (6) in the female the pelvis is wider, shallower, has an oval inlet, has a larger subpubic angle, the obturator foramen is triangular (oval, in the male), the tuberosities of the ischia are everted; (7) the inclination of the shafts of the femora from the pelvis to the knee is greater in the female.

PHYSIOLOGY.

2. *Functions of the pneumogastric nerve*: "Throughout its whole course the vagus contains both sensory and motor fibers. To summarize the many functions of this nerve . . . . it may be said that it supplies (1) *motor* influence to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory* and, in part, (3) *vasomotor* influence, to the same regions; (4) *inhibitory* influence to the heart; (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands; (7) *excito-motor* in coughing, vomiting, etc." (Kirkes' *Physiology.*)

3. In the *embryo,* the red blood corpuscles are derived from cells in the vascular area of the mesoblast; in the *adult,* they are derived chiefly from the red marrow of bones, also from the spleen. Their function is to carry oxygen from the lungs to the tissues of the body; this is accomplished by the hemoglobin, which has a great affinity for oxygen.

5. Foods are classified as follows:

I. Inorganic { Water. / Salts.

II. Organic { Non-nitrogenous { Carbohydrates. / Fats. / Nitrogenous—Proteids.

The constituents and functions are shown in the following table adapted from Notter and Firth's *Hygiene*:

Food.	Functions.
Proteids.	
1. All substances containing nitrogen, of a composition identical with, or nearly that of albumin; proportion of N to C being nearly as 2 to 7.	Formation and repair of tissues and fluids of the body. Regulation of the absorption and utilization of oxygen. May also form fat and carbohydrate, and yield energy sometimes. In most foods the above, both animal and vegetable, are largely converted into albumoses and peptones during digestion.
2. Substances containing a larger proportion of N are apparently less nutritious; proportion of N to C about 2 to 5½.	These perform the above functions less perfectly, or only under particular circumstances.
3. Extractive matters, such as are contained in the juice of the flesh.	These substances appear essentially as regulators of digestion and assimilation, especially with reference to the gelatin group.

Carbohydrates.	
Substances containing no N, but made up of C, H and O; the O being exactly sufficient to convert all the H into H_2O.	Production of energy and animal heat by oxidation. Form fats and possibly some proteids.
Fats.	
Substances containing no N, but made up of C, H and O; the proportion of O being *less* than sufficient to convert all the H into H_2O.	Supply of fatty tissues, nutrition of nervous system; supply of energy and animal heat by oxidation.
Salts.	Support of bony skeleton, supply of HCl for digestion, regulation of energy and nutrition.

7. Proteids are a group of organic bodies which are never absent from living animal or vegetable cells, to whose "life" they are indispensable. They are composed of carbon, hydrogen, oxygen, and nitrogen; most of them also contain sulphur, some contain phosphorus, and others iron, copper, or iodine. The molecule is very complex and its constitution is unknown.

8. The quantity of urine secreted depends upon:—the amount of liquids ingested, the amount of perspiration secreted, the temperature and moisture of the surrounding atmosphere, increase or decrease of blood pressure, and the presence or absence of certain diseases such as diabetes, nephritis, etc.

CHEMISTRY.

1. Potassium permanganate is a very active oxidizing agent; and its action as a disinfectant is due to the oxidation of the organic matter with which it comes in contact.

2. *A simple test for organic impurities in water*: "Put a pint of water into a *perfectly clean* quart bottle, cork and shake strongly, remove the cork, and inhale the air of the bottle. If the water be much contaminated, and if the observer's sense of smell be acute, an offensive odor will be observed. This method is *quite* rough, and only very bad water will produce an odor."—(Witthaus' *Essentials of Chemistry*.)

3. The reaction of cow's milk is amphoteric or alkaline when freshly drawn, but soon becomes acid; the reaction of mother's milk is alkaline or amphoteric.

4. The *inorganic constituents of the gastric juice*, are: water; hydrochloric acid; chlorides of sodium, potassium, and calcium; and phosphates of calcium, magnesium, and iron.

5. *Urea* has the formula $CO(NH_2)_2$; it "crystallizes in transparent needles or four-sided prisms, without Aq; permanent in air; odorless, having a cooling, slightly bitter taste, resembling that of saltpeter. Soluble in an equal weight of cold water, very soluble in boiling water and in five parts of cold or one part of hot alcohol, the solutions being neutral in reaction. At 248° F. it melts, and slightly above that temperature is decomposed. It is found in the blood, chyle, lymph, humors of the eye, saliva, perspiration, bile, milk, serous fluids, amniotic and allantoic fluids, and especially in the urine.

"It is the principal product of the oxidation of protein substances in the animal body, and is the form in which most of the nitrogen is excreted."

Uric acid has the formula $C_5H_4N_4O_3$; it "crystallizes in small, colorless, rhombic, rectangular, or hexagonal plates, or in rectangular prisms. As crystallized from the urine, it is more or less colored by the urinary pigments, and the angles of the crystals are rounded to produce lozenge shapes, which are arranged in bundles, crosses, or daggers.

"It is odorless, tasteless, very sparingly soluble in H_2O, insoluble in alcohol and ether, soluble without decomposition in H_2SO_4 or HCl. Moist uric acid has an acid reaction. It is a dibasic acid."—(Witthaus' *Essentials of Chemistry*.)

6. Hydrogen dioxide: *Formula*, H_2O_2.

Properties: It is a colorless, syrupy liquid, heavier than water, with a metallic taste; it is a powerful oxidizing agent, and a good bleacher and disinfectant.

Uses: Disinfectant, antiseptic, and bleaching agent; as an oxidizing agent; for renovating old oil paintings, and bleaching hair.

7. The most important chemical tests in the analysis of urine, are: the tests for albumin (heat, and nitric acid test); sugar (Fehling's, Trommer's, Boettger's, Nylander's, phenylhydrazin); bile, blood, indican, chlorides, phosphates; and quantitative for urea and uric acid.

8. Cream of tartar is monopotassic tartrate; Glauber's salt is sodium sulphate; Epsom salt is magnesium sulphate; copperas is ferrous sulphate; sugar of lead is lead acetate; common salt is sodium chloride.

9. In poisoning by corrosive sublimate, white of egg should be administered in not too great a quantity; and this should be followed by an emetic.

10. (1) *Oxalic acid*, occurs as oxalate of K, Na, Ca, etc., in the juices of rhubarb, sorrel, oak, etc. (2) *Malic acid* occurs in apples, pears, cherries, etc. (3) *Citric acid* is obtained from lemon juice. (4) *Gallic acid* is obtained from nutgalls.

MATERIA MEDICA AND THERAPEUTICS.

1. Senna is obtained from the leaves of the Cassia acutifolia. It is *indicated* in constipation, as a cathartic and a laxative.

Preparations: Confection, syrup, fluid extract, compound infusion; also compound licorice powder.

2. Three drugs that may be used to increase the flow of urine: water, spirit of nitrous ether, and caffeine.

3. For *chronic eczema of the gouty type*:

℞

Potassii acetatis
Potassi citratis aa ʒi.
Aquæ destillatæ q.s. ad ʒiv. Misce.

Sig.: One tablespoonful in water, after each meal.

4. In acute opium poisoning, by the mouth: Wash out the stomach with a dilute solution of potassium permanganate, and leave about three-quarters of a pint of the solution in the stomach. Maintain respiration, and give strong coffee.

5. Alkalies given before meals increase the secretion of hydrochloric acid in the stomach; if given after meals, some of the acid secreted is neutralized.

6. Ammonium carbonate may be used: as a gastric stimulant, as a cardiac and general stimulant, as an emetic, an expectorant, and a carminative.

It should be exhibited in small doses, which can be frequently repeated if necessary.

8. In diabetic coma a full dose of magnesium sulphate may be given.

9. *Three styptics*: Alum, silver nitrate, and tannic acid.

10. *Some therapeutic aims of the hot pack*: To cause sweating, to remove poisons and fluid in renal disease and uremia, to relax muscular spasm, to relieve excitement and insomnia of nervous origin.

PHYSICAL DIAGNOSIS.

1. Decreased resonance of the percussion sound over the lung may denote: Consolidation of the lung, presence of a tumor, fluid in the pleural cavity, collapse of the lung, phthisis, pneumonia, abscess of lung.

2. Dullness or flatness in Traube's area denotes effusion into the left pleural cavity.

3. Amphoric resonance is present in: pneumothorax, or a cavity in the lung.

4. Cracked-pot sound may be due to: a cavity in the lung communicating with a bronchus, pneumothorax connected by a fistula to a bronchus; it may be present in pneumonia.

5. Bronchial breathing is present in: Consolidation of the lung, pneumonia, tuberculosis, compression of the lung by pleural effusion.

6. Friction sounds are found in: pleurisy or pericarditis; also in hepatic or subphrenic abscess.

7. *Caput Medusæ* indicates portal obstruction, and is present in: ascites, tumors of abdomen, cirrhosis or tumor of liver.

8. *Tachycardia* is present in: Fevers, valvular cardiac lesions, phthisis, exophthalmic goiter, chlorosis, pernicious anemia, locomotor ataxia, arthritis deformans, sexual and alcoholic excesses.

10. The murmur of mitral insufficiency is soft, blowing, systolic, heart loudest at the apex, and is transmitted through the left axilla and posteriorly to the angle of the left scapula. The second pulmonic sound is accentuated.

PRACTICE AND PATHOLOGY.

3. Failure of compensation in chronic valvular disease of the heart may be marked by: Dyspnea, hemoptysis, cough, chronic bronchial catarrh; congestion of the stomach, intestines, and liver; dyspepsia, gastritis, enlarged spleen, ascites; cyanosis; dropsy; scanty and albuminous urine, with casts; clubbed fingers; vertigo, headache, or syncope.

	Amount of Urine Excreted in 24 Hours.	Specific Gravity.
In health	About 50 ounces	About 1015 to 1025
Acute nephritis	Greatly Diminished	Raised
Chronic parenchymatous nephritis	Diminished	Somewhat raised at first, then lower.
Chronic interstitial nephritis	Increased	Low
Diabetes mellitus	Enormously increased	Usually raised.

7. (*a*) *Decrease* of hydrochloric acid in the gastric juice indicates chronic gastritis, gastric dilatation, beginning carcinoma. (*b*) *Increase*, denotes gastric ulcer.

9. For the diazo reaction two solutions are required: (1) A saturated solution of sulphanilic acid in a mixture of 50 c.c. of hydrochloric acid and 950 c.c. of water, and (2) a 0.5 per cent. solution of sodium nitrite.

To make the test, 1 c.c. of (2) is added to 40 c.c. of (1), and the mixture thoroughly shaken. Equal quantities of this mixture and the urine to be tested are shaken together in a test tube, and 1 c.c. of ammonia is then floated upon the surface, when, in an affirmative result, a red band is formed at the junction of the fluids.

Its diagnostic value is uncertain. Von Jaksch "disclaims for this test any clinical importance whatever." Others have claimed that the reaction is pathognomonic of typhoid; but it has been found in other diseases besides typhoid—namely, phthisis, pneumonia, measles, scarlet fever, smallpox, and malaria.

As to *prognosis* it is said: that if the reaction is not found in the second or third week of a typhoid fever, the case is a mild one; (2) in phthisis a constant reaction implies an incurable case.

SURGERY.

8. The *indications, for enucleation of the eye*, are: "(1) Injuries of the ciliary region, when the eye is completely blind, or the traumatism so extensive that the form of the eyeball cannot be preserved; (2) traumatic iridocyclitis, to prevent or cure sympathetic ophthalmia; (3) severe pain in a blind eye; (4) irido-cyclitis, phthisis bulbi, and glaucoma, when accompanied by severe pain or inflammatory symptoms, and when the eye is blind or is certain to become so; (5) malignant tumors, either intraocular or epiocular, if they cannot be removed with retention of the eyeball; (6) anterior staphyloma, if the eye is blind, troublesome, and disfiguring; (7) panophthalmitis, after the suppurative stage is passed; (8) foreign bodies in the eye when they cannot be removed and cause irritation, or the eye is blind."—(May's *Diseases of the Eye.*)

GYNECOLOGY.

2. *Three causes for the suppression of menses*: (1) Pregnancy; (2) chlorosis; (3) imperfect development of the genital organs.

4. *Lacerated perineum* may be followed by local tenderness, irritable scar, reflex disturbances, subinvolution of the uterus, rectocele, cystocele, prolapse of the uterus, and incontinence of feces.

OBSTETRICS.

1. As soon as the nuclei of the germ-cell and sperm-cell have conjugated the ovum divides into two cells, called *blastoneres*. These divide and divide again until a mass of small cells results, called the *morula*, which is not much larger than the original ovum. These small cells now become differentiated into larger granular elements in the center and smaller clear cells at the periphery, the two being separated by fluid. The latter accumulates until the morula becomes converted into a vesicle, the wall being formed of a single layer of the small peripheral cells, the central mass floating free in the fluid, attached to the outer layer at only one point. The embryo is developed from this central mass. It is at this stage that the ovum is called the *blastodermic vesicle*.

4. *Cephalic version is contraindicated in*: (1) Contracted pelvis; (2) when rapid delivery is required; (3) rigid uterus; (4) immobility of the fetus.

Podalic version is contraindicated in: (1) Extreme contraction of the pelvis; (2) impaction of the presenting part; (3) when the retraction ring of Bandl rises two inches or more above the pubes.

5. *In pregnancy*: the total quantity of blood is increased; the white corpuscles are increased, as is also the hemoglobin; the red corpuscles are said by some to be increased, by others to be decreased; there is an increase of fibrin and extractives.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 22, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	437	153
Diphtheria	157	12
Measles	66	5
Scarlet Fever	72	5
Smallpox	—	—
Varicella	13	—
Typhoid Fever	132	14
Whooping Cough	17	7
Cerebrospinal Meningitis	7	3
Malarial Fever	—	—
Totals	901	199

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending August 21, 1908:

THE INFLUENCE OF OVERWEIGHT AND UNDERWEIGHT ON VITALITY.*

BY BRANDRETH SYMONDS, M.A., M.D.,

NEW YORK.

CHIEF MEDICAL DIRECTOR, THE MUTUAL LIFE INSURANCE CO. OF NEW YORK.

WHEN your committee asked me to prepare a paper on some topic connected with life insurance for this meeting of your society, I was embarrassed to choose a subject which should prove of general interest. The subject should be one which contained a minimum amount of figures with a maximum amount of information and which should be of interest to all. The influence of overweight and underweight upon vitality seems to combine these facts. This subject can be handled with only a few figures if you will accept some assertions in place of figures. Furthermore, the profession as a whole does not realize its importance, nor the dangers which beset those who are far removed from the correct standard of weight, whether above or below. In life insurance we have to measure these dangers for commercial reasons.

In 1836 Quetelet[1] published a table of heights and weights based upon the facts gathered from the examination of a moderate number of Belgians. His data were few in number and mostly taken from young people. The table shows one height and one weight for each year represented, and those are supposed to be the average height and weight for that year. Thus at age 20, the average height is 5 feet 7 inches and the average weight is 143; at age 30 the average height is 5 feet 8 inches and the average weight is 151. These isolated facts agree fairly well with our standard, but they are so imperfect that they are of little practical use.

In 1846 Hutchinson and Stevens published his table of heights and weights, also based upon certain data gathered in England by statistics. It purports to represent the standard weight for each height at age 30, and is as follows:

TABLE I.

5 ft. 0 inches	120 pounds
1 "	126 "
2 "	133 "
3 "	139 "
4 "	142 "
5 "	145 "
6 "	148 "
7 "	155 "
8 "	162 "
9 "	169 "
10 "	174 "
11 "	178 "
6 ft. 0 "	

For heights from 5 feet 3 to 5 feet 9 it agrees with our present standard at age 30. For the shorter heights it is too light, and for the taller height it is too heavy. This table was soon adopted by insurance companies as a guide. Each medical department had its own set of rules by which to calculate the proper weight for other ages than 30. These rules were based upon theoretical considerations and did not give very satisfactory results.

The army and navy have tables of the maxima and minima of both heights and weights by which they select recruits for the different branches of these services. These tables are intended to secure efficiency in physical development, which is above the average of even life insurance risks. For that reason they would not serve as a standard, even for the few years which they cover.

In 1897 Dr. George R. Shepherd compiled for the Association of Life Insurance Medical Directors a table of height and weight for each quinquennium from 15 to 69. This was based upon the heights and weights of 74,162 accepted male applicants for life insurance. The weight included the clothing and the height the shoes. In other words, the conditions were as these applicants presented themselves to the medical examiner. Many of the figures were undoubtedly estimates, but the estimates were usually made by trained men. These results were checked by the actual measurements of 5,250 accepted male applicants carefully obtained at the time of examination in one office. The two sets of figures substantially agreed, showing that the estimates were in accordance with the actual facts. At the extremes of age and of height, the number of individuals in any one class was quite small and the curve of weight showed abrupt changes which had to be equalized. The net result was a table of heights and weights varying according to age which was adopted by the leading insurance companies as being the standard.

TABLE II.

HEIGHT AND WEIGHT AT DIFFERENT AGES.

Based upon an Analysis of 74,162 Accepted Male Applicants for Life Insurance, as Reported to The Association of Life Insurance Medical Directors, 1897.

Ages	15-24	25-29	30-34	35-39	40-44	45-49	50-54	55-59	60-64	65-69
5 ft. 0 in.	120	125	128	131	133	134	134	134	131

*Read at the One Hundred and Forty-second Annual Meeting of the Medical Society of New Jersey, June 18, 1908.

...900 a tab... according to age of heights and weights varying the Medical Sections compiled by a committee of Congress. This was of the National Fraternal 133,940 applications based upon an analysis of United States and Canad selected risks from the marvelously the table cda. It corroborated almost In fact, there are 111 compiled by Dr. Shepherd. possibilities in the two tabcidences out of 112 with the chairman of this comes. Correspondence that this miracle was naturalmittee convinced me

In view of these two recordsand legitimate. tained and based upon over 200,(independently ob- in the United States and Can)00 healthy males may safely assert that we now ha, I think we standard of height and weight, vary ave a correct to age, of men in the United States ing according

It will pay to glance over this and Canada. moment. You will note that the table for a steadily as you go down each vertica eight rises Dr. Oscar H. Rogers[3] has formulated t column. from a study of this table that each adde he rule in height calls for an addition of 3 per ce inch the weight. This rule will apply, if libert in interpreted, to all but the small man. The weig lly increases steadily with the age in each horizontal t line up to the year 45 among the little men, the year 50 among the middle-sized men and the year 55 and even 60 among the tall men. One is almost tempted to say that the taller the man the longer it takes him to reach full maturity as shown by his weight. In the very tall this rule does not seem to apply, but the number of these were so few that a small error may have crept in. The largest number of individuals was found at 5 feet 8 inches of height, and this is true for all ages below 60. The age-period showing the largest number of individuals was the decade 25-34, and this is true for all heights.

In the case of women our standard is not yet assured. Dr. Shepherd analyzed the records of 3,016 female applicants accepted for insurance. This number is too small to give accurate results. In general the record shows that at the age of 20 women are lighter than men by six to nine pounds. This difference gradually diminishes with advancing age. By the time the menopause is reached, it becomes one or two pounds only, and after this it may be obliterated.

We must remember that these heights and weights were taken when the parties were shod and clad in ordinary clothing. The shoe of a man will ordinarily raise him about 1 or 1¼ inches. The weight of his clothing, including shoes, but excluding any form of overcoat, varies considerably according to the season. In the neighborhood of New York a man of 5 feet 7 inches during the summer will wear 6 or 7 pounds of clothing, while in winter this may rise as high as 12 or 14 pounds. This difference is undoubtedly a factor in the increase in weight during the winter which so many people believe in. For life insurance purposes we do not attach any great importance to the differences due to clothing, for they are not large enough to modify materially our results.

It is a curious fact that the lowest death rate does not coincide with the standard. In general terms it may be said that the lowest death rate is found in the class who are about 5 per cent. below the standard, but in the ages below 30 the lowest rate is found among those who are 5 to 10 per cent. above standard. The differences are not great, and I wish to discuss in fuller detail the more marked cases of overweight and underweight.

Here I must interpolate a definition. The word "mortality," when used in this paper, means the ratio of actual deaths to expected deaths. We calculate the deaths which are expected to occur in a given group of individuals by means of a standard mortality table, usually making an allowance for the benefits of selection in the early years of insurance. This process is quite intricate and need not be given in detail. If this group of individuals shows 1,000 actual deaths and 2,000 expected deaths, the mortality is 50 per cent. If the group shows 2,000 actual deaths and 1,000 expected deaths, the mortality is 200 per cent.

A—Let us first take up overweights. A case is not considered overweight unless it is more than 20 per cent. above the standard weight for the height and age. For example, at age 40 the standard weight of a man 5 feet 6 inches tall is 150 pounds. We would not regard him as an overweight until he had passed 180 pounds, which is 20 per cent. in excess of his standard weight. Even in the classes of smaller excess than this the mortality is increasing, but at this point it begins to be a serious matter. The effect of overweight is influenced by two fundamental factors. These are: (1) Percentage of overweight; (2) age of the individual. It may be said that as the t... percentage of overweight at a given age increases, age... e mortality rises with it. Take, for example, age... 40. The standard weight for a man of this poun... 5 feet 6 inches tall, is 150 pounds. At 180 pounds... s he is 20 per cent. in excess and at 195 a large... y he is 30 per cent. in excess. If we take weigh... group of men of this height and age who that our ... etween 180 and 195 pounds, we will find expected de... ctual deaths will be 112 as against 100 then, has ju... eaths. The mortality of this group, crease the w... mped up to 112 per cent. If we in- more than 19... eight of each of these individuals to in excess of t... 5 pounds, it is more than 30 per cent. the actual deat... he standard, and we now find that 130 as against ... hs in this heavier group will be words, the morta... 20 expected deaths. In other 130 per cent. ... ty has risen still further to

Take for another... mple age 65. The standard weight for a ma... tall, is 180 pounds. ... this age, 5 feet 11 inches per cent. in excess and ... 216 pounds he is 20 cent. in excess. If we t... 34 pounds he is 30 per of this height and age ... large group of men and 234 pounds, we wi... veigh between 216 deaths will be 126 as again... that our actual The mortality of this gro... xpected deaths. to 126 per cent. If we inc... has jumped each of these individuals to m... e weight of it is more than 30 per cent... 234 pounds, standard, and we now find tha... ss of the in this heavier group will be 172 ... al deaths pected deaths. In other words, ... t 100 ex- now reached 172 per cent. Exa... ality has multiplied, but these will suffice to ... could be mortality increases markedly as the ... that the above 20 per cent. in excess, and to a s... it rises degree when the weight passes 30 pe... reater excess. This holds true for all heights ... t. in ages above 30 years. ... all

Age is another factor of consequence, or... esent moderate degree of overweight is not a detrimen... among those younger than 30. People of the age of 22 who are 20 per cent. to 30 per cent. in excess, will give a mortality of 87 per cent. only. This mortality is not much larger than that of well-selected lives. When the weight at age 22

rises to over 30 per cent. in excess, the mortality rises to 109 per cent. This, of course, is unfavorable, but compare it with a mortality of 130 per cent. at age 35 and of 172 per cent. at age 65 in the same degree of overweight.

It may be said, then, that moderate degrees of overweight in persons below age 30 are not harmful, provided the party does not get actually heavier with advancing years. You will note that this remark refers to actual weight and not relative weight. Our standard increases with advancing age so that an excess of 33 per cent. at age 22 is almost exactly equal to an excess of 20 per cent. at age 45. If a boy, 22 years old and 5 feet 9 inches tall, weighs 199 pounds, his weight is 33 per cent. above the standard of 150 pounds at that height and age. When that boy gets to be 45 years old and his height and weight still remain the same, we now find that his weight is only 20 per cent. in excess, for the standard at age 45 is 166 pounds. He has just kept at the edge of the danger zone, and people of his class will give an almost uniform mortality, moderately in excess of the normal irrespective of age.

Beyond 30 years of age the mortality among overweights rises rapidly with the age and with the weight. This will happen in spite of the utmost care in examining and selecting the risks. Nothing seems to help these cases as a class. Even a long-lived ancestry only reduces the excessive mortality a little, but does not bring them within normal bounds. On the other hand, several other conditions make for the worse. A short-lived ancestry is bad. A tuberculous family history is not bad in the younger ages, for it might be supposed that the overweight would tend to overcome a tuberculous predisposition. Increasing abdominal girth is a very serious addition to overweights, and when this exceeds the expanded chest, the mortality is markedly increased. Any other blemish, whether in the personal history or in the physical examination, regularly increases the mortality of these overweights.

In the case of women we must make our standard a little lighter than that of men, as stated in the beginning of this paper. Having done this, overweights among women are found to be just as bad as among men; in fact, a little worse. They are fewer in number, for women take greater pride in their shape, and do not often allow themselves to become fat, showing in this their superior wisdom.

As regards foreigners, it may be urged that our standard table is based entirely upon selected lives in the United States and Canada, and that it would not aply to another race, like the Germans, who are usually stouter and heavily built. We have found, however, that overweight foreigners are, if anything, a little worse risks than overweight natives. In truth, human fat seems to be the same wherever found, and has the same effect upon the prospects of life, whether in England, Germany, Holland, Belgium, France, Italy, Mexico, or the United States.

B—Now, let us consider the effect of underweight. As long as the weight is not below 80 per cent. of the standard, *i.e.* not more than 20 per cent below the standard, the effect seems to be slight. The mortality rises slowly, especially among the younger ages, but the increase is gradual and not alarming. Below this level, however, the mortality rises to a point where it is of consequence, especially in the younger ages.

Below 20 years of age we can expect a mortality of 118 per cent. when the weight is from 80 to 75 per cent. of the standard, *i.e.* 20 to 25 per cent. below the standard. Ages above 20 years in this group show a fairly uniform mortality of about 95 per cent. As you see, this is not very bad, but, on the other hand, is not very good.

In the next group, in which the weight ranges from 75 per cent. to 70 per cent. of the standard, *i.e.* from 25 to 30 per cent. below the standard, the number of entrants in my company below age 20 numbered only 30 in the 30 years from 1870 to 1899. This number is too small to furnish any figures of consequence. Even in the decade 20-29 the total number of exposures only amounted to 299, an average of less than 30 for each year. These gave 2 deaths as against 1.9 expected. The numbers are too small to be of consequence. In the decade 30-39 the number exposed rises to 1,391, and these give a mortality of 100 per cent. After this the mortality is fairly satisfactory, ranging from 90 to 95 per cent.

For weights below 70 per cent. of the standard, *i.e.* more than 30 per cent. below the standard, our experience is very limited and too small to divide into different age periods. The actual deaths amounted to 12 and the expected to 13.5, showing that our selection was reasonably good. The number of entrants below age 40 was too few to give any information. Above age 40 we can only say that when they are picked with care, these extreme underweights live a good while.

As regards the other factors which modify the influence of underweight, we have to deal with a problem quite different from that of overweight. The influence of age is reversed among underweights. The younger ages are the ones most affected, while the older ages are but slightly disturbed.

The mortality increases as the weight diminishes, but even among those who are more than 30 per cent. below the standard, the mortality is not excessive.

The association of dyspepsia with underweight is a serious matter with those below age 25. This combination will give us a mortality as high as 150 per cent. I have no doubt that dyspepsia and underweight together in the young is often indicative of incipient tuberculosis, the extent of which is so small that it is not determined on physical examination.

The association of underweight and tuberculous family history has long been recognized as serious, especially in the younger ages. Thus, we find that this combination gives a mortality of 180 per cent. in the ages below 35. Above that age the influence of tuberculosis depends upon the number of cases in the family. If we have 2 or more cases occurring in the family of an underweight, the mortality is 107 per cent. for all ages above 35. In these older ages the underweight who has had only one case of consumption in his family runs but little risk, perhaps for the reason that he takes better care of himself.

As regards women, we must make allowances in our standard weights for the sex. We then find that the lesser grades of underweight from 80 to 75 per cent of the standard give a mortality of only 77 per cent., an excellent result and practically uniform for all ages. For weights below this the mortality becomes bad, in fact over 100 per cent., but the cases are so few that no deductions can be made from them. There is no reason to suppose, however, that underweight women are any worse than underweight men, and

I have no doubt that they will give as good a mortality if selected under the same circumstances.

As regards residence, I regret to say that I have no figures pertaining to foreign underweights, nor have I been able to find any statistics. From a general empirical knowledge of risks, native and foreign, I think it reasonable to assume that foreign underweights have about the same mortality as native underweights.

C—It is of interest to the profession to know from what causes these overweights and underweights die, for none of them ever dies of obesity or emaciation. There were 1,499 deaths among the male overweights and 1,078 among the male underweights. These numbers are sufficiently large to enable us to subdivide them into all the important classes and most of the leading individual classes. I will compare these deaths with the figures obtained by Dr. E. J. Marsh, a former president of this society, from the entire male mortality of the Mutual Life Insurance Company.[4] It is proper to do so, for these deaths form a small part of the material which he used. We will, therefore, be comparing results which are homogeneous so far as their origin is concerned. Any differences may be ascribed to the influence of overweight or underweight. These differences are in some cases considerable and of much interest.

TABLE III

SHOWING THE PERCENTAGE OF DEATHS IN ALL CLASSES AND SOME INDIVIDUAL DISEASES AMONG OVERWEIGHTS, UNDERWEIGHTS AND THE GENERAL EXPERIENCE OF THE MUTUAL LIFE INSURANCE COMPANY

	Causes of Death	Overweights	Underweights	General Experience
Class I	General Diseases—Acute	9.67	9.28	8.90
	Typhoid fever	4.00	3.06	3.94
	Malarial fever	1.27	1.21	1.24
	Influenza	1.47	2.04	1.00
Class II.	General Diseases—Chronic	13.07	24.59	19.56
	Tuberculosis	2.93	16.98	12.42
	Cancer	4.40	5.57	4.18
	Diabetes	3.40	0.65	1.25
Class III.	Diseases of the Nervous System	19.08	12.16	17.44
	Cerebral Congestion and Hemorrhage—Cerebral Softening, Paralysis	14 14	8.47	12.32
	General Paralysis and other forms of mental alienation.	1.80	0.84	1.30
Class IV.	Diseases of the Circulatory System	16.01	11.69	11.85
	Organic diseases of the heart.	12.94	8.54	10.76
Class V.	Diseases of the Respiratory System	8.54	15.78	11.86
	Pneumonia	6.87	12.34	9.03
Class VI.	Diseases of the Digestive System	10.61	8.54	10.19
	Cirrhosis of Liver	3.47	0.65	1.00
Class VII.	Diseases of the Genitourinary System	12.01	7.42	8.78
	Bright's Disease and Nephritis	11.07	5.30	6.66
Class IX.	Diseases of Skin and Cellular tissue	1.20	0.47	0 50
Class XI.	Old age	None	2.04	1.50
Class XII.	Violent causes	7.07	5.57	7.42
	Casualties	4.20	3.43	5 21
	Suicides	2.87	2.14	2.20
Class XIII	Ill defined	2.60	2.50	3.98

The class of acute general diseases includes all the acute infectious diseases except a few which are distinctly localized, like pneumonia. Overweights suffer a little more from these than underweights, the experience of the latter being nearly identical with the general experience. Typhoid fever shows a little better among the underweights, while malaria is about the same in both. Influenza is a little worse in both than in the general experience.

Overweight seems to secure a marked degree of immunity from tuberculosis, for we find among them not one-quarter of the amount of fatal tuberculosis which we find in our general experience and hardly one-sixth of what we find among the underweights. The large amount among the latter is partly due to the fact that the underweight was only a symptom of a tuberculosis, which was not recognized at the time of the examination. After allowing for this, however, we are tempted to say that underweight predisposes to tuberculosis or rather to fatal tuberculosis, and the reverse is the case with overweight.

Cancer among overweights and underweights, men and women, shows no appreciable difference from the general experience.

Diabetics are scarce among the underweights, hardly one-half of the general experience, but they are five times as numerous among the overweights.

If we group together the different forms of cerebral congestions and hemorrhage, cerebral apoplexy and paralysis, we find that overweights are a little in excess as compared with the general experience, while the underweights are distinctly below the average in this group. This difference also holds true for the various forms of mental alienation, grouped together.

Organic diseases of the heart show a decided excess among overweights, and as great a deficiency among underweights.

Pneumonia is nearly twice as fatal among underweights as among overweights, although the prognosis in pneumonia is usually regarded as more serious in an overweight than in an underweight. Taking these two factors into account, it would almost appear that overweights have a certain immunity from the pneumococcus, while the underweights are more than usually susceptible.

Cirrhosis of the liver is three and a half times as prevalent among overweights as in our general experience. This undoubtedly points to alcoholism, for statisticians generally consider that hepatic cirrhosis is a very accurate index of the alcoholic habits of a class. Among the underweights it is below the normal, as are also the other diseases of the digestive system, thus showing their moderation in food as well as drink.

Bright's disease, both acute and chronic, is nearly twice as prevalent among overweights as in our general experience. This excess can probably be ascribed to the habit of overeating and overdrinking, which produces both the overweight and the Bright's disease. Among underweights it is a little below the average.

In Class IX there were eleven deaths from carbuncle among the overweights, where there should have been but two. This is a great excess, but I am inclined to think that many of these cases were associated with unrecognized diabetes, which would be properly described as the cause of death. If this surmise is correct, diabetes becomes a still more serious factor among overweights.

Casualties among both overweights and underweights are a little below the average. This may show that they take care to avoid injuries, or else it may be that the abnormal weight, whether above or below the standard, prevents them from entering occupations liable to fatal accidents.

No overweight, whether man or woman, died of old age or senility according to our record. On the other hand, old age or senility caused 22 deaths among the male underweights and 5 among the female. Furthermore, it should be noted that no overweight attained the age of 80 years at death, while, on the other hand, 44 underweights passed this age, and two of them even reached the age of 90 before dying.

Deaths among the women, whether overweight or underweight, were too few to permit any elaborate criticism. In so far as the small material could be analyzed, it corroborated the male experience in both classes. No deaths occurred from puerperal causes among the underweights, and only 4 among the overweights, this being about the average experience of the company among women.

D—Now, let us sum up in a general way the differences between overweights and underweights. The mortality among all those, irrespective of age, who are between 20 and 30 per cent. below the standard weight, is 96 per cent., while the mortality of all, irrespective of age, who are between 20 and 30 per cent. above the standard, is 113 per cent. These figures alone would show that overweight is a much more serious condition than underweight. On the other hand, we must take into account the fact that until recent times overweights were accepted more freely by insurance companies than underweights. To put it in another way, underweights were selected with more rigid care than overweights. The old idea that an overweight had a reserve fund to draw upon in case there was a run on his bodily bank was prevalent, although it was recognized that excessive fat might be harmful and should exclude the risk, on the ground, perhaps, that it was a form of capital which was not active. Similarly, an underweight was considered to be undercapitalized, and if his bodily bank had to go through a panic like pneumonia, or hard times like organic heart disease, he would become insolvent and bankrupt. As a result of this method of thought, our underweight mortality is rather better and our overweight mortality rather worse than if both sets had been accepted under exactly the same conditions. But, even if we make full allowance for the difference in selection, I am convinced that the same percentage of overweight is a more serious matter than if it were underweight. The excessive weight, whether it be fat or muscle, is not a storehouse of reserve strength, but it is a burden which has to be nourished if muscle, and which markedly interferes with nutrition and function if fat. This does not apply to the young, those below 25 years of age. Here a moderate degree of overweight is much more favorable than underweight. In fact, up to age 25 an overweight not to exceed 110 per cent. of the standard is upon the whole good for the individual. It seems to indicate a certain hypernutrition and robustness of physique which is favorable to the subsequent life. Underweight among these young people, on the other hand, is unfavorable, and in some cases indicates commencing disease or the tendency thereto. But when we pass the age of 30 these conditions are reversed and the difference between overweight and underweight in their influence upon vitality becomes more marked with each year of age.

Of course, for the best interests of health, one should be near standard weight, and that is the sermon which you should preach to your patients. Impress upon them the advisability of their being within 10 per cent. of the standard, for within that range is found the lowest mortality and the greatest vitality.

CONGENITAL UMBILICAL HERNIA, WITH REPORT OF CASE.

By W. EDWARD MAGRUDER, M.D.,
BALTIMORE.
ASSOCIATE PROFESSOR OF PEDIATRICS AND CLINICAL MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS.

Moynihan (Encyclopedia Medica, Vol. IV., 1900) describes the formation of umbilical cord hernia as follows: "At the beginning of the third month of intrauterine life the viscera become enclosed in the abdominal cavity by the growth of the visceral plates. If the growth is defective, the visceral enclosure is more or less incomplete and hernia results. The term hernia, as Malgaigne suggests, is inappropriate, for we are not concerned with viscera escaped from a cavity, but with viscera which have never entered it."

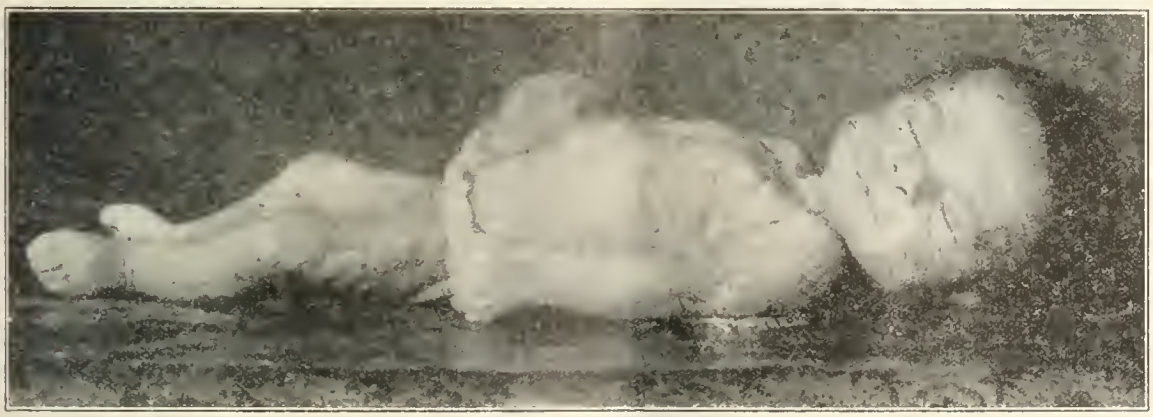

Fig. 1.—Congenital umbilical hernia.

Three classes of hernia are described: (*a*) Where the gap at the umbilicus is small, hernia of the root of the cord; (*b*) where the gap is moderate in size, sacculated hernia; (*c*) where the abdominal wall is grossly incomplete (eventration), the viscera having a thin covering derived from the amnion. The case described below belongs to the last variety.

Lindfors (*American Journal of the Medical Sciences*, October, 1889) states that this condition occurred once in 5,184 births at the Munich Maternity Hospital, between 1862 and 1881. Accord-

ing to Wollstein (*Archives of Pediatrics*, 1904). Block saw one in 5,000 births at Berlin Charité, and Vienna did not see a case among 3,043 births at the Paris Charité. The following is the report of the case:

Colored female child, delivered normally on August 6, 1903. Mother was fifteen years old, of healthy parents, and of a family of seven children of normal development. Father was one of three boys, of about her age, and, as she was uncertain which one to blame, the paternal history could not be obtained.

Last menstruation was on January 1, 1903, which made the term exactly seven months.

She was seen on February 27, when a history was obtained of attack of violent cramp in right inguinal region on the preceding day, followed by a fainting spell with unconsciousness for two hours. A boggy mass was found in the right tubal region, extending well down into Douglass' cul de sac, pushing the uterus to the left. Cervix was soft; abdomen rigid. Arrangements were made to have her moved to a hospital for observation, but she failed to go, and was next seen in labor on August 6, when she was suffering from general anasarca with extreme edema

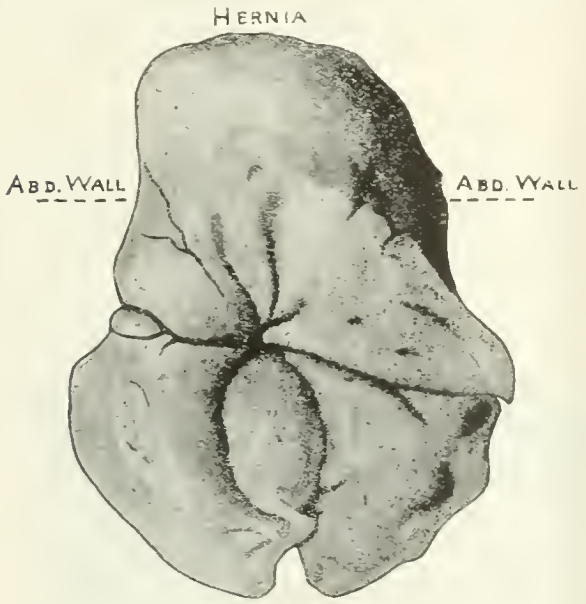

FIG. 2.—The liver in the case of umbilical hernia.

of the vulva, which her mother claimed had existed for three weeks. Twenty minutes after delivery of the placenta she had convulsions, and remained in a stupor for three hours.

The child was found to have solid tumor larger than half an orange in the region of the umbilicus, covered by what appeared to be a continuation of the membrane of the cord, and this entered the abdomen below and to the left of the tumor.

The infant died at the end of forty-eight hours, having peculiar convulsions, involving the hands and arms. In spite of the fact that very little cyanosis was observed until just prior to death, we were unable to make the child cry.

The covering of the tumor had sloughed off and exposed part of the liver, which proved to be the contents of the hernial sac.

A photograph was made by Dr. Laciar and autopsy performed by the writer sixteen hours after death. The organs proved to be normal and no malformations were found except of the liver, which was shortened from above downward, and had its right lobe compressed into a rounded mass and pushed through the abdominal wall at the umbilicus. The liver weighed 120 grams, and its peculiar shape is well shown in the drawing by Dr. Palmisano (Fig. 2). The cord entered the abdominal cavity to the left of the tumor with the arteries and vein coming together slightly below the surface.

A full discussion of the views of Cruveilhier, Simpson, Muller, Scarpa, Richter, Aschoff, and others, concerning the causes of this malformation, may be found in Wollstein's report, and much additional information may be gained from Cumston's comprehensive article in the *British Journal of Children's Diseases*, November, 1905.

The contents of these herniæ vary, and, according to Cumston, a few loops of small intestine alone may be present, or the cecum, as well as most of the large intestine, may be in the sac. The stomach, pancreas, spleen, liver, and kidneys have all been found outside the abdominal cavity. Cases in which the heart and part of one lung are prolapsed must be classified as true eventration. The size of this variety of hernia varies greatly, and the tumor may be so large as to interfere with delivery. It is usually covered by amnion, Wharton's jelly, and peritoneum.

Cumston states that the arteries and veins quite frequently become united at the apex of the tumor forming the cord, but the insertion of the cord does not always take place at the apex of the tumor. Usually the cord occupies one of the sides, and, according to Cruveilhier, the insertion is found more frequently on the left. It often happens that in these cases the elements of the cord, arteries, and vein are thrown to the same side, instead of being disassociated. In cases of irreducible hernia the insertion preferably takes place at the apex of the tumor. In forty-five cases, where the point of insertion of the cord was given, Buschan found the following: Thirteen times in the middle of the tumor, once on the right of the tumor, and twice on the left, on the anterior aspect of the tumor once, and on its lower aspect twenty-eight times. This same authority makes the remark that the cord is usually very short, and Otto has described a case where it was completely wanting, the hernial sac being directly adherent to the placenta. A similar case has been described by Thorner.

Operation for the cure of these malformations was suggested by Oken in 1810, but no record is found showing that any successful operations had been performed at this time. Malgaigne, writing in 1840, speaks of this variety as being of merely pathological interest.

According to the statistics of Linford and others, expectant methods of treatment have proved unsuccessful, and early operative interference has reduced the mortality to a large extent.

J. M. Elder (*Montreal Medical Journal*, April, 1903) collected statistics of nineteen cases which had been operated upon with modern technique, of which seventeen recovered and two died; and of nine cases, treated by compression, of which six died.

A review of the reports of 160 cases, which I have been able to find in a thorough search of the literature, shows 126 were operated upon, of which 84 recovered and 40 died, the results in the other two cases not having been known.

Operations proposed for the radical cure of congenital umbilical hernia, including those of Dorhm, Olshausen, Carl Breus, Lawson Tait, Quenu, Condamin, Duplay, Dauriac, and others, are fully described by Cumston, who summarizes as follows: "As to the method to employ for the radical cure, I do not believe that any one can be considered the

TABLE I.—CASES TABULATED BY MICHAELIS (*Berliner Klinik* 1906, HEFT 222.)

Surgeon	Reference	Sex	Description	Treatment	Course	Remarks
Putz	Dissert. Halle, 1891.	Male	Swelling size of man's fist. Orifice of hernial sac 16 cm. in circumference.	Laparotomy performed under chloroform anesthetic 24 hrs. after birth.	Cure in 21 days.	
Reymond	Medical Record, 1896.			Immediate laparotomy.	Died soon after	Liver weighed 130 g. Diameter of hernia, 6 cm.
——			Swelling size of child's head. Small and large intestines. Liver.	Laparotomy performed 24 hrs. after birth.	Cure.	
Steinbüchl	*Archiv. f. Gynakol.* 1900.		Size of walnut. Loops of small intestine.	Olshausen's method.	Died of ileus	
Kennedy	*Brit. Med. Jour.*, 1901.		Swelling size of an apple. Cecum, appendix, small intestine.	Laparotomy performed 12 hrs. after birth.	Cure.	
——			Size of an egg. Loops of small intestine.	Laparotomy performed 1 hour after birth.	Cure.	
McDougall	*Brit. Med. Jour.*, 1902.		¼ in. in diameter.	Single ligature. Protective dressing.	Died	Premature birth.
Lotheissen	*Wiener kl. Rundschau*, 1903.		Swelling size of an apple. Ileum, cecum, ascending colon.	Laparotomy without anesthetic 24 hours after birth.	Cure in 8 days.	
Alder	Dissert. Zurich, 1903.	Male	Liver. Intestines. Circumference of base 24 cm. Height 10 cm.	Laparotomy under chloroform anesthetic 3 days after birth.	Died.	
Kinlt	Dissert. Leipzig, 1904.	Female	Swelling larger than abdomen of the child. Liver, stomach, spleen, entire intestinal tract	Laparotomy 10 days after birth.	Died.	Reposition impossible.
——		Male	Oval in shape. Diameter at base, 4 cm. Liver, loops of small intestine.	Laparotomy 10 hrs. after birth.	Died 5 days after.	
Zillmer	*Zeit. f. Geburtsh. u. Gynäk.*, 51 B.		Prolapsed lobe of the liver.	Laparotomy. Reduction of prolapsed liver lobe.	Cure	
Hedmann	*Centr. f. Chir.*	Male	Size of an egg. Loops of small intestine.	Ligature and excis'n 5 hours after birth.	Died later of dyspepsia.	
——				Laparotomy 6 hours after birth.	Cure.	
Küstner	*Medicinische Klinik*, 1906.			Laparotomy.	Cure.	
Ladenburg	*Centr. f. Chir.*, 1906.			Laparotomy 5 hours after birth.	Died.	
Kongel	*Deut. Med. Woch.*, 1906.		Size of pigeon egg perforating Meckel's diverticulum.	Laparotomy, resection of intestines 3 days after birth.	Cure.	
——			Size of fist. Liver, large part of intestines.	Laparotomy when few hours old. Two oper. on account of intestinal fistula.	Died.	
Stevenson	*Centr. f. Chir.*, 1906.		Unusually large. Large intestine, large part of small intestine. Meckel's divert'l'm.	Laparotomy 24 hrs. after birth.	Died.	

TABLE II.—CASES NOT IN ANY OF THE PREVIOUS TABLES, BUT COLLECTED BY THE AUTHOR OF THE ACCOMPANYING REPORT.

Surgeon	Reference	Sex	Description	Treatment	Course	Remarks
Knoop	Samml. kl. Vortr., 1903. No. 348.		Swelling size of walnut.	Operation.	Cure.	Operation without anesthetic. Reduction of hernia and closure with catg
Knoop	Samml. kl. Vortr., 1903. No. 348.	Male	Sac contained liver.	Operation.	Cure.	Chloroform anesthetic. Incision through peritoneum and reduced hernia. Clos'd with silver wire. Healed by granulation.
Guizeit	*Deut. Zeit. f. Chir.*, 1904. V. 73.		Size of hernia, 5 x 6 cm. Oval. Increased in size when child cried. Sac contained liver up as far as the suspensory ligament.	Operation. No anesthetic.	Cure.	Operation postponed for 3 days. Peritoneum opened. Closed with catgut. W'nd closed with silk. Healed by granulation.
Wollstein	*Arch. of Pediatrics*, 1904.	Male	Tumor large as small pear. Sac contained cecum with vermiform appendix and 3 inches of ileum.	No operation.	Died	Prolapsed ileum showed a Meckel's diverticulum half an inch in height.
Michaelis	*Berl. Klinik*, 1906. Hft. 222.	Female	Larger than fist. Base size small plate. Transparent covering. Sac contained omentum, liver coils of small intestines.	Under chloroform, incision and reduction, which was difficult. Jaundice followed. Removed dressing at end of 6 days.	In 3 weeks w'nd had healed and child was OK. Nine mo. later child seen and well.	
Michaelis	*Berl. Klinik*, 1906. Hft. 222	Male, 5 days old.	Mother insane. Sac not translucent. Fibrin within. Could not make out contents on account of fluid, which was reduced, and coils of intestines and part of liver felt. Child had hare lip and cleft palate. Temperature sub-normal.	Died before it could be operated upon.	Died	Autopsy showed sac to contain dark fibrinous liquid, part of small intestine, cecum and appendix, part of ascending colon, and part of left lobe of liver. Adherent. General peritonitis.
Michaelis	*Berl. Klinik.*, 1906 Hft. 222.	Male	Cyanotic child. Tumor little larger than apple. Covering thin. Could see loops of small intestine.	Operated upon by Carl Breus. Incision. Sac empty, having reduced spontaneously. Ligatured.	In 3 weeks discharged well. Child seen in Clinic freq'tly aft'w'ds and found well.	
Nove-Josserand	*Lyon Méd.*, V. CVIII, 1907		Hernia size of an orange. Sac contained small intestines and almost entire liver.	Operation at end of ten hours.	Cure	Intestinal obstruction followed about seventh day after the cutting of a small adhesion which had permitted the accumulation of blood in upper part of wound.
Wilson	*Western Med. Rev.* V. XII, 1907.	Male	Sac contained entire small intestine and cecum firmly united by adhesions, forming a tumor about the size of an orange.	Operation under chloroform when child was 3 hours old.	Cure	

TABLE II.—(Continued.)

CASES NOT IN ANY OF THE PREVIOUS TABLES, BUT COLLECTED BY THE AUTHOR OF THE ACCOMPANYING REPORT.

Surgeon	Reference	Sex	Description	Treatment	Course	Remarks
Klots	*Transvaal M. J.*, V. 2, 1896–7.	Female	Sac contained liver, intestines and omentum. Cord ran peripherally.			Premature fetus of 7 months apparently dead just before birth. Beside omphalocele showed spina bifida.
Klots	*Transvaal M. J.*, V. 2, 1906–7.	Male	Hernia large. Cord ran peripherally. Sac contained liver, intestines and omentum.			Has seen this malformation twice in 1,986 confinements. Case reported, child was stillborn at term and showed all the signs of congenital syphilis.
Meredith	*N. Y. Medical Journal*, V. 86, 1906.	Male	Large pear-shaped tumor, 7 x 8 x 8 cm. Contained large portion of small intestines, cecum with its appendix.	Operation	Cure	Reduction. Entire sac was resected. No vomiting. Bowels moved. Stitches removed on twelfth day. No indications of recurrence.
Meredith	*N. Y. Medical Journal*, V. 86, 1906.	Female	Large oval tumor 10 x 12 x 12 cm. Tissue had thin, translucent and somewhat myxomatous appearance. Contained liver and apparently the entire gastrointestinal tract. Irreducible.	No operation	Died day after birth.	
English	*Lancet*, Nov. 11, 1905.	Female	Swelling size of tangerine orange. Contained small intestine, one part of which consisted of a blind diverticulum adherent to sac wall.	Laparotomy	Died	Post-mortem examination. Local peritonitis had commenced around neighborhood of diverticulum. Intrauterine adhesions had occurred between Meckel's diverticulum.
Moran	*Am. J. Surg.*, V. XIX, 1905–6.	Male	Elliptical, translucent tumor at root of cord about size of baseball.	Radical operation under chloroform 2 hours after birth.	Cure.	
Doolittle	*Canada Lancet*, V. 39, 1905–6.	Male	Sac ruptured. Entire intestinal tract from duodenum to sigmoid flexure lying partly in and partly out of sac. Opening connecting sac with the abdominal cav. about ¾ in. in diam., almost completely filled with sec. of large and small intest.	No operation	Cure.	
Jones	Trans. Rhode Island Med. Sec., V. 7, Pt. 1, 1904.	Male	Irreducible tumor at umbilicus size of lemon. Sac very thin. Contained 3 coils of ileum, the cecum with appendix, the ascending transverse and a portion of the descending colon.	Operation 16 hours after birth.	Cure	Operated on under ether anesthetic.
Veron	Bul. I. Soc. Scient. et Méd. de l'Ouest., 1904.	Male		Operation	Died	Malformations of the intestines.
				Operation	Cure.	
Piollet	*Lyan Méd.*, CIII, 1904.	Female	Embryonic hernia. Spheric in shape, large as adult hand.	Operation	Lived for 15 days.	
Spencer	Trans. Path. Soc., Lond., V. 49.	Male	Pedunculated egg-shaped swelling covered with gangrenous skin.	Operation under chloroform	Cure	Serous covering of hernial protrusion had become infected. No question of any form of treatment other than immediate operation
Elder	*Montreal Medical Journal*, 1903.	Male	Tumor size of orange. Dull on percussion. Sac contained cecum with appendix, ascending and transverse colon, about half small bowel.			
Michaelis	*Berl. Klinik*, 1906. Hft. 222.	Male, Newborn.	Swelling about size of hen egg. Covering necrotic.	Operated upon immediately. Made 2 elliptical incisions around tumor. Sac cont'd greater part of left lobe of liver, which was adher't to walls of sac. Replaced cont'ts and sutured.	Died on day after operat'n.	Autopsy showed fluid in pericardium and twist in liver, which had resulted from efforts at reduction.
Michaelis	*Berl. Klinik*, 1906. Hft. 222.	Male, 7 days old.	Cord about size of half dollar. Tumor size of hen's egg. Covering dry and parchment like. Diarr. and vomiting.	Not operated upon.	Died third day.	Autopsy showed cecum and appendix attached to wall of hernia. Ascending colon with fecal fistula.
Michaelis	*Berl. Klinik*, 1906. Hft. 222	Male	Cyanotic child. Swelling size of man's fist, larger on crying Covered by skin except at apex, which was covered by translucent membrane. Contained coils of intestine apparently of large gut. Peristalsis. Had hypospadias and congenital heart lesion.	Parents objected to operation. Treated by compression.	Died of some acute infect'n at 8 months.	
Koller-Aeby	*Arch. f. Gynæk.* V. 82, 1907.		Hernia 13 x 15 cm. Oval, shape of eyeglass. Contained part of left ventricle		Premature, died 3 hours after birth.	Hernia was diverticulum of the heart. Posterior surface of diverticulum was covered with peritoneum
Ringel	*Münch. med. Woch.*, V. 54. 1907.		Sac contained part of colon, cecum and part of liver.	Operation without anesthetic.	Died	One day old when brought to hospital. Wound heal'd 10 days after operation Died eighteenth day from sepsis.
Ringel	*Münch. med. Woch.*, V. 54. 1907.	Male	7 cm. long. Contained Meckel's diverticulum and 2 coils of small intestine.	Operation without anesthetic.	Cure	Four days old when brought to hospital. Meckel's diverticulum. Peritoneum closed in operation.
Fiedler	*Deut. med Woch.* V. 33. 1907.		Circumference 22 cm. Tumor of hard consistency. Contained whole liver and several coils of small intestine.	Operation when child was 5 days old.	Cure	Adhesions between liver and peritoneum.
Ritterhaus	*Deut. Zeit. f. Chir.* V. 89. 1907.	Male	Hernia extended from ensiform cartilage to pubis. Sac contained meconium. Stricture of anus.	Operation under chloroform.	Died 12 hours after operation.	
Ritterhaus	*Deut. Zeit. f. Chir.*, V. 89, 1907.	Male	Sac contained part of stomach and whole of liver.	Operation under chloroform.	Died 9 months after operation.	Post-mortem examination showed adhesion between liver and abdominal cav
Ritterhaus	*Deut. Zeit. f. Chir.*, V. 89, 1907.	Female	Swelling size of mark. Contained part of small intestine.	Operation	Unknown	Hernia reduced. Operation 3½ hours after birth.

TABLE II.—(Continued.)

CASES NOT IN ANY OF THE PREVIOUS TABLES, BUT COLLECTED BY THE AUTHOR OF THE ACCOMPANYING REPORT.

Surgeon	Reference	Sex	Description	Treatment	Course	Remarks
Ritterhaus	*Deut. Zeit. f. Chir.*, V. 89, 1907. *See-i-Kwai Medical Journal.*, Tokyo, 1904, V. XXIII. A case of cong. umbilical hernia.	Female	Sac contained greater part of small intestine.	Operation	Cure	Hernia reduced.
McColl	*Dominion Med. Monthly*, 1907, V. XXIX. Congenital umbilical hernia with report of case.					
Fiusterer	*Wiener kl. Woch.*, 1906, V. XIX.					
Brodfûhrer	*Med. Woche*, 1903. A case of congenital umbilical hernia.					
Coenen	*Berl. kl. Woch.*, V. XLIV, 1907.					

best, and it is well to make a selection among the various techniques according to the given case. In reference to Mayo's method, which in the adult is, according to my way of thinking, superior to any other, I have done this operation eighteen times without recurrence; it has been purposely not alluded to when discussing the radical cure of congenital hernia, because it cannot be readily applied with any chance of success on account of the necessary resection of the tissues which it involves. Generally speaking, simple laparotomy, with extirpation of the sac and suture of the freshened borders of the wound, will be sufficient in a large majority of cases. As to the use of several layers of buried sutures, I can say from practical experience that, although they may be practised successfully in the adult, they are far from being easy in newly born children. The question now arises as to when a congenital umbilical hernia should be operated on, and, in reply to this, I would say that it should be done as soon as possible after birth, because desiccation of the sac will soon become the starting-point of inflammatory attacks in the viscera. If the operation is carried out carefully and without undue loss of time, babies will stand the operative shock and anesthesia well."

Safford (*Philadelphia Medical Journal*, February 23, 1901) reported a case and published a table made up of those previously tabulated by Linford, Hallet, and Berger, and additional ones collected by him from the literature up to 1900, making in all 90 cases. Yates and Davis (*American Medicine*, Vol. II., 1907) have tabulated 15 cases, and I have found reports of 36 cases in the literature not included in any of the previous tables.

In addition, Michaelis (*Berliner Klinik*, 1906. Heft 222) reported 26 cases, 19 of which, not having been previously reported in English, are tabulated below.

922 Madison Avenue.

REPORT OF A CASE OF BRAIN TUMOR, WITH AUTOPSY.*

By MORRIS J. KARPAS, M. D.

NEW YORK.

ASSISTANT PHYSICIAN, MANHATTAN STATE HOSPITAL, WARD'S ISLAND.

The following extremely interesting case recently came under my observation:

The patient, Mrs. Melanie B., was admitted to Manhattan State Hospital on August 20, 1907, and on the next day transferred to my service, where she remained until the time of her death.

There is no history of vesanic or neurotic taint in her family or its collateral branches. Lues in the husband and neoplasm in her ancestors could not be ascertained.

The patient was born in France in January, 1864. The development of her infancy and her childhood was uneventful. At the age of four or five she fell off a horse and sustained an injury to her left hip and ever since then her gait was limping. When six years old she received a trauma to one of the parietal regions of her head (a bottle was thrown at her head) but apparently at that time no ill effect was noticed.

She received a fair education; she could read and write French. About fifteen years ago she came to the United States. Here she learned English readily and was soon able to speak, read, and write it. Before marriage she was employed as a cook, in which capacity she showed proficiency.

She married at the age of twenty-nine: she gave birth to no children and had no miscarriages. She was treated gynecologically for a number of years, and twelve years ago she was operated upon for some uterine affection, the nature of which is not clearly known (probably curettage, as it was done at home). She was always pleasant, agreeable, highly generous, and diligent. The climacterium did not occur.

So far as it can be determined the first evidences of her malady became manifest in 1904, when she began to have convulsive seizures, which varied in frequency and intensity. At first they appeared once a week, and later she would have them several times a day.* For the past three years she suffered with headaches and was quite often troubled with emesis. It was also noticed that she became seclusive, somewhat cranky, and would frequently make peculiar remarks to her husband.

In November, 1906, the symptoms of her disease became aggravated. She commenced to talk in a bizarre manner, and one night she woke up her husband and told him "I want to see those loafers—I know what I want to say, but I can't tell you." On the next day when her husband put on his clothes she said: "Take your coat off, this belongs to my husband." During this time convulsions were more frequent and her speech became affected. She was unable to find proper words for the expression of her thoughts. She could not name objects, but

*Read before the New York Neurological Society, May 5, 1908.

*The informant described the convulsions as general, but later thought that the right side was more involved.

identified them correctly when their names were suggested to her. She lost her ability to read or write French and English. She vomited more often, headaches became more severe, and at times she would exclaim "I have pains in my head, I cannot suffer so much, I would rather die." Evidences of rightsided paralysis were observed in the early part of November, 1906. She grew gradually ataxic in gait and station, and on account of her poor physical health she was sent to Bellevue Hospital, whence she was transferred to Manhattan State Hospital.

Here physical examination revealed the following: There was slight facial asymmetry, the left side of face being somewhat elongated and its muscular contraction apparently more active than on the opposite side. The tongue protruded in the median line and grips were equal; in raising her arms she lifted the left one much higher than the right; the extensors and flexors were satisfactorily tested. The left lower extremity was decidedly shorter than the right one and its general musculature was in a state of atrophy. However, this condition was due to an injury which she received in her early childhood. Gait was limping, she dragged her left foot; station was slightly ataxic. Elbow, supinator, and wrist reflexes were active. Knee jerks were unequal, but brisk (right was less active than left). Ankle jerks were present. Patellar reflexes were unequal (left more active than right). No ankle clonus; Babinski's reflex was present on the right. Corneal reflexes were much diminished. Stereognosis was doubtful. Reaction to pin pricks was more marked on the left than on the right side. Distinct tenderness to percussion was elicited on the left side of the cranium. Internal strabismus of the left eye; pupils were equal, irregular in outline, and the reaction to light was sluggish, but the accommodation reflex was good. On the first examination by Dr. Ward A. Holden optic disks were normal, but later only a slight optic neuritis was demonstrable. According to Dr. Adolph Meyer there was a suspicion of a right hemianopsia, for she did not react to feinting on the right side, nor did she notice objects on that side till the median line was reached. Hearing was more acute in the left ear than in the right. Examination of the cerebrospinal fluid revealed the presence of serum albumin and a moderate lymphocytosis (an average of twelve cells in a field). Heart and lungs were without grave pathological lesions. No arteriosclerosis; blood pressure 125.

The patient was quiet, did not seem to recognize her new environment, and showed no acute depression. General inactivity was in evidence. She was unable to grasp the meaning of questions and her speech was somewhat rambling. Her orientation was apparently affected. The following answers to questions will illustrate her peculiar trend of thought:

What place is this? "My husband does not know where—where I am—somebody else put me here—I don't like here—I want to go away."

What place is this? "This is a house for people to be swept here."

Are you sick? "A young man made me stay here yesterday, I was sick before. I ask everything of the girls but they don't give me away things I like to have my things."

Who am I? "He is a man who wants to do." (Makes gestures and does not complete her thought.)

Where were you born? "I don't know."

Have you had convulsions? "Yes—a long time ago."

Where were you born? "France."

How old are you? "Fifty-five."

Aphasic Examination.—Reaction to words heard. As a rule the patient could not understand what was said to her. However, at times she comprehended some questions, but framed her answers poorly. She was asked to take her shoes off, she complied with the request after the instruction was repeated. She was able to give her name. She could not perform complicated tasks and her comprehension in general showed considerable impairment.

She was unable to pick out objects as they were named to her. She handled certain things correctly, and especially with the left hand. A flute was shown to her, she immediately put it in her mouth, and blew into it.

She was asked several times to repeat words and sentences, but she failed to do so, except on one occasion she repeated the fourth word ("examine") of the sentence: "I wanted to examine you."

Spontaneity in speech was limited. Her vocabulary was meager. Now and then she would make irrelevant comments and only rarely her productions contained an intelligible concept. Once she dictated to the nurse the following letter in English:

"My dear husband: You didn't write to me—to write—to pay you know—the letter—she said—she has what she write you—the letter that you write me—I suppose I have—to you—have no mama—you know—yes that's all—that's it."

Some of her remarks were as follows: "I don't want to go with you (addressing her husband) because you put me here—it is a shame to put me here." "You (to husband) better go, otherwise he (pointing to the ward physician) will keep you here, I will go for money, you did not let me, I will give you back the money, you will write a letter for me, you know, this afternoon you write it your way—write my letter and send it because we are going to have rain soon (looking out of the window)." She could not enumerate the alphabet, count money, recite the Lord's Prayer, or spell words.

She was unable to recognize objects and only at times she identified few articles by their proper names.

Objects shown and patient's reply:

Watch—Thief.

Keys—I don't anything I want to get my clothes.

Glass—No.

Spoon—I don't see.

Knife—Knife.

Fork—Flowers.

Plate—To eat.

$10—$10.

$1—$10.

Rubber ball—This is to play with, I played enough with it.

Scissors—Paper.

The reaction to things smelled and tasted not ascertained.

She could not read or write either French or English.

The internal language was not ascertained, on account of lack of cooperation.

Paraphasia and perseveration were present.

Apraxia.—Patient showed some peculiar awkwardness in handling objects, and especially it was noticed in the right hand. She attempted to put on her underwear but was unsuccessful. She fumbled with her chemise, and could not understand how to get it over her head. In disgusted manner she threw the skirt down and the rest of her underwear and made no other effort. She adjusted her petticoat properly, but this was accomplished with

her left hand. She put on her wrapper wrongly, hindside foremost. The left stocking was put on correctly and without any difficulty, but in endeavoring to get on the right one, she placed the sole on the top of her foot. On another occasion she donned the skirt, wrapper, stocking, and shoes without any trouble, but this was done with the left hand. However, she was unsuccessful with her underwear.

During the months of September and October the patient was drowsy, fatigued, and somnolent. At times she moaned and groaned as if she were in great pain. She manifested no impulsive or assaultive acts, and at no times could hallucinations be satisfactorily defined. Quite often she would make a few incoherent remarks and occasionally would answer a question correctly. At no time, however, was it possible to engage her in a conversation. On November 2, 1907, at 4 A. M. patient had a general convulsion which was followed by coma. She had another convulsion about 1 P. M., and five hours later she succumbed to exhaustion.

The autopsy was performed two hours after death by Dr. G. Y. Rusk, to whom I am indebted for the following pathological report:

"The necropsy showed irregularly distributed purulent bronchitis in a few of the bronchi of the lower lobes with slight pulmonary edema. Chronic pelvic inflammatory disease with double hydrosalpinx, atrophic ovaries and small interstitial myomata.

The calvarium was symmetrical, averaged 4 mm. in thickness, the diploe was slightly deficient. An attempt was made to inject the brain, the results being only partially satisfactory. The brain was of good size (1,568 grams), convolutional markings normal in distribution. The convolutions appeared diffusely compressed, but especially in the region back of the frontal lobe of the left hemisphere. The left hemisphere was distinctly the larger, and on palpation one could roughly outline a solid mass, underlying the lower third of the left posterior central convolution and extending upward and backward beneath the supramarginal and angular gyri, then downward to the point of separation of the parietal and occipital lobes, then inward and forward towards the uncus, where an irregularly colored soft tumorous mass projected from the mesial end of the Sylvian fissure, compressing and causing considerable distortion of the left optic tract and also compressing the third nerve. There was considerable distortion (foreshortening and widening of the temporal lobe) and the firmness to palpation extended across the temporal lobe to the point of origin. The pons appeared flattened, the groove for the basial artery deep. The cerebellum was also compressed so that the vermis was almost entirely hidden. The markings of the pachyonian granulations along the longitudinal fissure were numerous; and numerous small pits, especially at the tip and along the lower edge of temporal lobes, marked points of adhesion to the dura.

After fixation, the brain was sliced into a series of blocks of about 4 mm. in thickness and the majority directly imbedded in paraffin. The limitation of the growth could not be made out macroscopically. The center and apparent origin of the growth, however, lay in the region of the left amygdala, where there was a large skim-milk appearing mass. From this point the growth infiltrated the remainder of the corpus striatum, the overlying island of Reil, the adjacent surface of the temporal lobe, the internal capsule, the thalamus, and apparently the centrum ovale, which, while not differing in color or consistency from the corresponding region on the opposite side, was relatively enlarged, as were the parts noted above as being infiltrated. The centrum ovale of the frontal lobe was also enlarged on this side and showed areas which were slightly more translucent, suggesting tumor infiltration as far forward as the anterior tip of the lateral ventricle. Posterior to the main growth, in addition to the areas noted above, the tumor proceeded along the cornu ammonis and infiltrated the mesial and inferior surface of the occipital lobe, especially the calcarine area and parts lying about it. From the region of the thalamus the growth infiltrated the tegmentum of the midbrain and pons, and also the crus.

Microscopically, the growth was a glioma chiefly of the small-celled type, although spider cells and the even quite fibrous areas containing few cells occurred. In spite of the extensive infiltration no areas of medulated fiber degeneration were seen; the growth itself also did not show areas of degeneration.

More exact demarcation by the microscope confirmed the gross description given above, and in addition it was found that the growth crossed the midline into the opposite thalamus; that the corona radiata was extremely infiltrated, and that in all directions the infiltration extended farther than the gross appearance would indicate."

Remarks.—The gradual development, insidious course, convulsive seizures, right side motor and sensory disturbance, headache, vomiting, drowsiness and somnolence, commencement of optic neuritis, hemianopsia, aphasia, paraphasia, alexia, and agraphia were unmistakable symptoms which pointed to a definite focal cerebral lesion, a neoplasm involving the left temporal parietal region. The following three atypical features, which are of great interest, are worthy of special emphasis: (1) Slight optic neuritis in presence of a marked intracranial pressure; (2) a relatively low blood pressure (120 to 125); (3) a moderate lymphocytosis and serum-albumin of the cerebrospinal fluid.

The last findings complicated the disease-picture to some extent and a syphilitic process suggested itself, but the therapeutic test eliminated this condition. The patient was subjected to antiluetic treatment, which produced no beneficial effect.

The question of operative procedure came under serious consideration, and Dr. Adolf Meyer, who examined the patient several times, thought that surgical interference was not indicated, and, in his own words: "The slow progression from an anomia to an involvement of reading and writing, and the general sensory path, and greater sensitiveness over the parietal region by tapping, point rather to an internal growth than to an operable dural growth or superficial process. The extent of the process and its localization in the temporoparietal area of the leading hemisphere would contraindicate any interference necessitating destruction of tissue."

The study of mental symptoms of cerebral tumors is extremely interesting, and merits careful and intelligent investigation in the field of neurology and psychiatry. The painstaking observations of Kraepelin, Schuster, Wollenberg, Gianelli, Knapp, and others show that psychical disturbances vary in every individual and depend a good deal upon endogenic psychopathic predisposition.

In the main, the mental manifestations accompanying brain tumors, in the majority of cases, are somnolence, inattentiveness, forgetfulness, poverty of ideas, indifference, fatigue, and general inability. Memory and judgment may not be affected. Not infrequently the mental picture may simulate that

of general paresis. Increased irritability, depression, idea of sin, and persecutory delusions may occur. Again, manic features may predominate, such as elation, distractability, flighty utterances, volubility, irritabilty, with childish cheerfulness and inclination toward jesting and humor (Witzelsucht). The relationship of physical disturbances to special localization of tumors of the brain is not yet definitely established.

In my case the mental symptoms were not striking, and most of them could be explained on anatomical grounds. The patient was irritable, depressed, and anxious. Her speech was incoherent, and at times she gave expression to a few ideas which suggested a persecutory trend, but these were not associated with any occurrences and were most probably purely incidental. At no time were hallucinatory reactions noticed, and *Witzelsucht*, rather a common symptom in brain tumors, was not observed.

I am under great obligations to Dr. Adolph Meyer, Director of the New York Pathological Institute, and Dr. George H. Kirby, Clinical Director of the Manhattan State Hospital, for their invaluable assistance rendered to me in the study and interpretation of the neurological and psychical manifestations of my patient. I wish also to acknowledge my hearty thanks to Dr. William Mabon, Superintendent of the Manhattan State Hospital, for the permission he has given me to report this extremely interesting case.

CASE OF OBSTRUCTION OF THE BOWELS, SIMULATING APPENDICITIS.

By J. McFADDEN GASTON, A.M., M.D.,

ATLANTA, GA.

Complications connected with the appendix are likely to occur at any time. It has fallen to my lot to have a subphrenic abscess as a complication, and this has been reported (Medical Record) to the Southern Surgical and Gynecological Association. The absence of an appendix and the presence of Meckel's diverticulum has been met by some surgeons, among others, Dr. A. L. Wright, of Carroll, Iowa. It is instructive to note that the case seen and operated upon by Dr. Wright was first considered by him one of appendicitis. When he operated, he found no appendix, but not far from the location for it, discovered a protrusion something on the order of a blubber, which proved to be a Meckel's diverticulum. He was surprised to find this condition, and regarded it as a strong indication for an operation for removal. An illustration is given by him which enables the reader to see a double viscus apparently distended with gas.

I did not see the report of this case until after I had encountered one very similar to it, but his case is so important in explaining my own, that I give a short abstract of it.

He had found little on the subject of the diverticulum giving rise to pathological changes sufficient to call for surgical interference, and is very positive that the average surgeon would not be able to make a diagnosis of the diverticulum before operating. He mentions the "sudden onset of the attack, the pain coming on gradually and rapidly increasing in severity until almost unendurable, at first diffused throughout the abdomen, and then becoming localized in the right side of the iliac region. The pain always present on making firm, deep pressure, a little later vomiting, with elevation of temperature and pulse. This picture gradually yielding to a full dose of morphine, followed by a thorough cleansing of the intestinal tract with salines." Such a condition presented itself in his case—of a young man, aged 27, farmer, married, who had always enjoyed good health until two years before. His first attack was while he was at work in the field, where he was suddenly taken with severe abdominal pain. The pain extended over the entire abdomen, but gradually became localized in the lower right quarter of the same. Another physician saw him during this attack, and Dr. Wright did not elicit very much information except that he had had fever and that he had vomited several hours after the commencement of the attack, corresponding to the disturbance of the stomach in appendicitis.

In cases of intestinal obstruction, the stomach rejects whatever is put into it immediately after the commencement of the attack, usually within the first two or three hours, while in appendicitis the patient does not vomit until after several hours have elapsed.

The man had three attacks like the one just described in one year, and with each attack he was worse. The last attack occurred about six weeks before admission to the hospital where Dr. Wright treated him. The abdomen became tympanitic and excessively painful over the appendix. The patient was confined to his bed for about a week at this time and was entirely incapacitated for manual labor. Any attempt at physical exertion promptly started the pain in his side and informed him of the penalty in store provided he did not heed the admonition. The physicians who saw him all made a diagnosis of appendicitis and advised operation, but he was apparently in good health otherwise and did not undergo any operation in the interval until he did consent to have the appendix removed and entered the hospital for that purpose, and was operated upon April 13, 1899. In trying to bring up the appendix, a loop of the ileum was seized, and, when brought into the abdominal wound, had a Meckel's diverticulum about three inches long attached to it. He found the tissues of the diverticulum and the surrounding portion of the ileum so thin and attenuated that he decided to excise the greater portion of the intestinal canal adherent, and the divided ends were brought together with a Murphy button. The young man made an uneventful recovery, passing the button on the nineteenth day, except that there was a leak.

This unusual case was matched by my own in the absence of the appendix, but Wright does not mention a band of any kind, which has so often been found in other cases, and which was the source of trouble in my own case. Dr. Wright regarded the diverticulum as of traumatic origin, probably from internal violence, causing the muscular coat to give way sufficiently to allow the mucosa to insinuate itself between the fibers and raise the peritoneum. I think it is more probable that these cases are of congenital origin. The ascending colon was much shorter than normal, and the small intestine joined the larger at or near the liver. The distal end of the diverticulum was about one inch in breadth, thickened and quite rough, as though the seat of several inflammatory contests, although attachment had never taken place between

it and the surrounding viscera; the proximal end was very much smaller and accounted for the obstruction that he had.

In drawing a parallel between the above case and my own, which I shall describe further on, I would call attention to the fact that I was unable to encounter the colon and cannot explain it on any other ground but that it was, as Dr. Wright has explained, very short, and that the connection between the small intestine and the colon may have been beyond the point where I could draw upon the mesentery. It must be remembered that the colon has no mesentery, but contains a band like a ribbon running down the length of it, and that it is very easily recognized and nearly always protrudes through the wound where the abdomen is opened, as for operation in appendicitis.

The last case that I operated upon for appendicitis was that of a young lady about 28 years old, who had suffered from appendicitis in recurrent attacks until we became convinced that an operation should be done in the interval. In this case the colon was very much in evidence, and could be traced for a considerable length, and was the means of locating the appendix, which was found doubled up and adherent to the walls externally, as though enclosed in a little box. In her case the ileum was not distended particularly and was collapsed, she having been carried through the preparatory treatment of laxatives and enemas until ready for the operation; but in striking contrast to this, and the average case of appendicitis, was the very distended ileum and jejunum in my case of obstruction, with absolutely no trace of the colon. I cannot think that I could have searched without discovering the colon. Yet the history of cases of obstruction is that when the obstruction is above the colon, the distention is above also, and so the colon would naturally have been collapsed and out of sight, but could and would have been drawn up at the ileocecal valve by the traction that I placed upon it had there not been some abnormal condition.

The presence of Meckel's diverticulum itself was one that I diagnosticated after much trouble, but corresponds very closely to the experience of Dr. Wright, who describes his case as having one end smaller than the other. The average surgeon might very well have removed this and called it the appendix quite possibly, so similar was it in appearance and in its position. In these cases diagnosis cannot be made by symptoms alone, and while there are many surgeons who have met with Meckel's diverticulum during operations in the abdominal cavity, I have failed to find one who has operated with the distinct diagnosis in advance of opening the abdomen. The inference is that it is very variable in its appearance and does not follow any fixed rule.

Dr. J. G. Earnest of Atlanta, Ga., has informed me that in about a thousand abdominal sections he has not encountered one single Meckel's diverticulum, and that the only one he has seen was one that was found by Dr. W. P. Nicholson of Atlanta, in operating for another trouble. The experience of Dr. John B. Roberts of Philadelphia is confined to about half a dozen cases, some of them being found in the deadhouse, but others being complicated with hernia.

Dr. Frank E. Bunts of Cleveland, Ohio, has written a very interesting account of one case that he had, and has given the literature on this subject very completely.

In a recent discussion before the New York Surgical Association, it has come out that it is not so uncommon in experience as one might think to meet this anomaly. Lavator is said to have been the first to record its having been observed, and Ruysh, as early as 1701, called attention to it in his "Thesaurus Anatomicus," giving it the name of diverticulum, but Johan Friedrich Meckel has been given the credit of first calling the attention of the profession generally to the diverticulum ilei, which he most clearly differentiates from the acquired pseudodiverticula occasionally found along the intestinal canal.

According to Bunts, the relative frequency of the occurrence of this diverticulum was noted by Rolleston, of St. George's Hospital, to be ten out of 337 cases examined, a percentage of 3.37. Osler observed it in 2 per cent. of cases. This percentage is in very close accord with that given by the collective investigation of the Anatomical Society of Great Britain and Ireland, and by Quain and Treves independently, and also by Mitchell. This relative frequency must be between 2 and 5 per cent., but the size varies more, and also the location of it. It does not seem, however, that the diverticulum is restricted to any particular portion of the intestinal canal, for it has been described as anywhere from the pylorus to the ileocecal valve, and to have been found in the cecal region as well as upon the esophagus. The term "diverticulum ilei" is therefore misapplied, according to Bunts, as it may occur in the jejunum in a considerable number of cases. I did not find any record of the shortness of the colon connected with these cases except as given by Dr. Wright. Lamb says it has been found seven times in connection with the duodenum, and refers to two cases in the Army Medical Museum. Fitz, in a paper on "Persistent Omphalomesenteric Remains," refers to the well authenticated case of duplication of the esophagus, small intestine, cecum, and colon, and explains such anomalies on the assumption of an abnormally high or low seat of the omphalomesenteric duct.

The length of the Meckel's diverticulum is in part dependent on the degree of involution the omphalomesenteric duct undergoes. The usual form encountered is the tubular variety, resembling the finger of a glove, and with a diameter nearly equal to that of the gut proper.

The patient of Dr. Bunts left the hospital on March 31, 1902, and was able to resume work. The button had not yet passed. I will not describe the case in full, except to say that he considered it a case of strangulated hernia in which the contents of the sac consisted only of a large Meckel's diverticulum and a portion of the wall of the small intestine, to which it was attached. The patient was a laborer, 23 years old, who entered Cleveland City Hospital January 28, 1902, suffering from severe pain in his right groin and frequent vomiting. The hernial sac was very tense, and was opened up and found to be filled with a dark bloody fluid and what appeared to be a single knuckle of the intestine, resembling more a moderate sized gall-bladder. The peculiarity of its shape led to the pulling out of more intestines from the hernial orifice, where it was sharply constricted; this required the resection of the intestine and the use of the Murphy button.

My own case was that of a young man aged 25, who, while working at his desk in the bank on October 20, 1907, was suddenly seized with violent pain in the epigastric region. He was carried into the directors' room, where he was laid upon a couch and a physician was called in hurriedly and ad-

ministered hypodermically morphine, 1/4 grain, atropine, 1/150 grain. This failed to relieve his symptoms and chloroform was administered. He was seized again with apparently uncontrollable pain, and with writhing and rigidity of the abdominal muscles.

I was called in to see him during this attack, which was about an hour after he had received the first hypodermic from the hands of Dr. E. D. Richardson of Atlanta. I decided to repeat the dose of morphine and atropine, and, this failing again to have the desired effect, I also gave him chloroform by inhalation from a handkerchief inserted in a tumbler. When he had been thoroughly anesthetized, I examined the abdomen by deep palpation with the left palm, and discovered a cord-like structure down in the pelvis and leading up towards the navel. This I conceived to be indication for an operation, which I supposed would be appendicectomy, and he was removed to the Presbyterian Hospital at twelve o'clock. There the nurses were instructed to take his temperature, pulse, and respiration every half hour, and to apply every three hours an ointment consisting of equal parts of belladonna, mercurial, iodine, and camphor ointments. His temperature was 97.2° at one o'clock, his pulse was 96, and his respiration 24. He was given calomel and bicarbonate of soda, one grain each, at intervals of two hours until six grains of calomel had been given, and this was followed by sodium phosphate. There was no action upon his bowels from this until an enema of soapsuds was given.

Monday, October 22, at 9 A.M., the urine was examined and the specific gravity was 1.030, albumin negative, sugar negative, microscopic examination negative, and reaction acid. He rested fairly well Tuesday, but there were evidences of a trouble in the character of the pulse and a haggard appearance of his face.

The case was reported to his father Saturday night, and on Monday evening the father arrived from Swaynesboro, Ga., and gave his consent to an operation. A consultation was held with Dr. J. C. Olmstead October 23, and he concurred in the advisability of an operation, but could not say positively what would be found, whether gall-bladder trouble or appendicitis.

The operation consisted of an incision along the margin of the rectus muscle, midway between the navel and the anterior superior spinous process of the ileum. A gridiron incision was made in the muscles of the region traversed and a final search made for the appendix. The various devices for encountering the appendix failed to show any, and as the ileum was greatly distended with gas, it was difficult to keep it from protruding through the wound. We discovered a band and considerable enlargement in the region where the appendix should be, and in order to ascertain more positively the condition of the viscera, this band and enlargement were left for the time being, in order to continue the search for any other complication. I felt the ileum carefully to the point of constriction by this band, and found the same place by a diagnosis of exclusion. This enlargement was found to be connected with the mesentery, and was ligated with catgut and excised, while the band was found to be a connection from the mesentery to the navel and vertebral column. This was severed, having been ligated on each end, one near the mesentery and one near the navel. No serious hemorrhage occurred, but a venous congestion caused an outflow of blood from the mesentery.

In examining the position of the ileum, a dark hue was encountered in the portion of it covering about six inches of the intestine. This was probably due to the constriction, and hot cloths having been applied and saline solution poured on them, the intestines were returned and the wound was closed with silkworm gut, and the operation was completed.

The patient sustained considerable shock, and saline solution was administered in the chest, when he rallied well from the operation. He was perfectly rational at 6 P.M., having some nausea from the anesthetic, but otherwise standing the anesthetic well. The great distention of the bowels occasioned pain, and he was given codeine 1/2 grain at 2 A.M. Wednesday.

His pulse at 4:15 P.M. Tuesday, after the operation, was 112 and respiration 20, but at 8 P.M. it had fallen to 88, with a temperature of 100° and respiration of 20. At 12 midnight his temperature was 101°, and at this time he was given four ounces buttermilk. He slept from two to three o'clock, and again at 6 A.M. slept about four hours, when the pain became unbearable, and hypodermics of morphine 1/4 grain were administered at hours, 7:30 and 10:05 A.M., and 8 P.M. Hot turpentine stupes were applied at 3, 4, and 5 P.M. Nourishment consisted in albumen, liquid peptonoids, and beef tea up to midday of Thursday, when the buttermilk was repeated. An alum enema was used for his bowels at 9 A.M. and at 4 P.M. of Thursday, October 25. They proved effectual in relieving the lower bowel. The patient was suffering, and a rectal tube was used at 11 P.M., when an enema of turpentine was effective. On Friday he had a temperature of 98.6° at 4 A.M., rising to 100.6° at 9 P.M. A mustard plaster was applied to the abdomen at 10:30 P.M. The occasion for using the mustard was the nausea and vomiting, which had been a feature of his case from the beginning. Often he had refused nourishment, but on this day, Friday, we attributed a part of his nausea to the administration of calomel 1/10 grain at 10:30, 11:30 A.M., and 12:30 P.M.

The incision was dressed on two occasions within the first week after the operation and presented no special trouble, except that union by first intention of the skin was not obtained, but the muscular fibers had united thoroughly, and no danger of hernia existed. A subcuticular suture of silkworm gut had been used and collodion cotton applied to bring the skin together. With the retching and vomiting the skin had been detached.

On Saturday he was again nauseated and received 1/8 grain morphine at 12:15, and 1/4 grain at 2:15, which relieved him somewhat. He did not require another hypodermic until 6:30 P.M., when codeine, 1 grain, was used, and morphine was not resorted to until midnight.

Sunday morning he was in better condition and was able to take a dose of oil. This relieved his bowels, but not until an enema was administered late in the evening.

From this time he began to improve, and on Monday and Tuesday he was comparatively comfortable, but for a certain amount of salivation due to the small doses of calomel. He slept all night Monday and Tuesday nights, and no opiate was needed for pain. The distention had subsided, and he was resting well, with every indication of complete relief.

The second week of the after-treatment of this case presented the feature of incomplete closure of the abdominal walls, which had to be dealt with by

daily dressings and the use of peroxide of hydrogen on the wound. Examination of the sutures showed that the silkworm gut had irritated the muscles externally, but that it had held very securely the muscular fibers internally.

A faithful report of the case requires the mention of this complication in the union, and the inference drawn is that silkworm gut should not be relied upon for all the layers of the muscular tissue. I have never had any trouble with kangaroo tendon, and I had intended to use it in this case, and had it ready, but in the hurry of closing up the external incision I did not do so. It is well to advise all students, however, that in closing an abdominal wound, it is better to have a ventral hernia even than to have a death on the table. This man had been through too much already to venture upon any cosmetic effect that might come from careful approximation of the surfaces. However, perfect union had taken place between the peritoneum and the internal oblique muscle, and the aponeurosis. The wound was examined a day or two after the operation and collodion dressing was left with every appearance of a complete closure of the skin, but this began to discharge some blood. It is possible that the blood was responsible for the irritation to the skin, and this is another point that has to be disregarded at times in operations of emergency where we would like to have no hemorrhage to interfere with the wounds; but we cannot always avoid leaving some ooze rather than delay to tie every small vessel. An ideal operation would be a bloodless operation and a union by first intention would result.

No antiseptic except saline solution was employed at the time of the operation in the abdominal cavity, but the skin was thoroughly disinfected and all necessary precautions taken for having a thoroughly aseptic operation. With the removal of the silkworm gut, all irritation seemed to subside, and the skin came together with every prospect of a good, substantial abdominal wall and no ventral hernia.

Some surgeons prefer silk to all other ligatures. Binnie says: "Silkworm gut is an ideal, smooth, strong, nonporous, nonabsorbable suture. It is easily sterilized by boiling, which, at the same time, softens it and renders it easy to tie."

I have no reason to regret having used it from one point of view, and that is its nonabsorbable quality and its strength, for it held in spite of great retching and distention.

On June 17, 1908, the patient was seen at his usual work in an Atlanta bank, and has enjoyed good health since the operation.

SIGMOIDITIS.

By MARTIN L. BODKIN, M.D.,

BROOKLYN, NEW YORK.

LECTURER ON DISEASES OF THE RECTUM AND ANUS, BROOKLYN POST-GRADUATE MEDICAL SCHOOL; RECTAL AND GENITO URINARY SURGEON, BROOKLYN HOWARD ORPHAN ASYLUM; ASSOCIATE SURGEON, ST. MARY'S HOSPITAL.

Diseases of the sigmoid flexure may be divided into simple and specific inflammations just as we recognize the many inflammatory processes in any portion of the intestinal canal. The sigmoid flexure is probably more vulnerable to these various manifestations of disease because of its peculiar anatomical construction and its physiological function. It may be the seat of, or there may be extending above or below, a simple catarrhal inflammation, namely acute or chronic colitis, or proctitis. There may be a specific disease such as gonorrhea, erysipelas, dysentery, tuberculosis, or syphilis. In addition, we may have the consideration of follicular colitis, ulcerative colitis, or secondary colitis.

Sigmoiditis and perisigmoiditis have their respective fields, so to speak, but the clinical reports of many writers on this subject have been confusing, and, with but few exceptions, of little value for classification, owing to an improper description of the diseases attacking this section of the intestinal canal. Many clinicians report cases picturing the manifold symptoms of a number of the different phases of the disease under one caption.

The sigmoid flexure is liable to secondary affections, which will not be recognized until each has been clearly understood with its relationship to the surrounding organs and tissue. It may be the seat of several quite ordinary inflammations which follow a definite course from a well-known origin.

So as to be definite, our consideration of sigmoiditis shall be of a single category, excluding dysentery, syphilis, tuberculosis, cancer, secondary sigmoiditis, and secondary perisigmoiditis. We use the term sigmoiditis and perisigmoiditis meaning the affection of the interior or exterior of the bowel, just as we speak of a typhlitis or a perityphlitis.

Sigmoiditis occurs in two simple forms, acute and chronic catarrhal inflammations, which are nonsuppurative.

Perisigmoiditis is either suppurative, which is acute in type, or nonsuppurative, which is chronic. One form may, however, merge imperceptibly into the other.

Affections of the sigmoid flexure are rarely seen before the twentieth year and are more frequent in the female than male. Scarlet fever and pregnancy are said to be predisposing causes.

Acute catarrhal sigmoiditis, nonsuppurative, attacks young adults most frequently. Intestinal parasites, foreign bodies, drugs, such as arsenic and corrosive sublimate, impacted feces, diverticula, intussusception, volvulus, and severe purging are mentioned as causes responsible for this disease. It resembles in character acute catarrhal proctitis. There is severe pain in the left iliac fossa, sometimes accompanied by a chill and rise in temperature, a coated tongue, and, possibly, peritoneal irritation; there are no bowel movements and but a slight amount of flatus will be expelled.

The acute symptoms may run the ordinary course of a catarrhal inflammation and subside within seven or eight days, or may become chronic. After the acute symptoms abate a sausage-shaped, painful, nonfluctuating mass, with its convexity to the right, may be felt. This mass may persist for a month or two after the attack. The clinical picture will vary in degree with the severity of the onset and may terminate in ulceration. The clinical history and manifestations will differentiate this affection of the sigmoid from a tubal disease or an appendicitis of the left side.

Chronic hypertrophic sigmoiditis may follow the acute catarrhal sigmoiditis and is essentially a hypertrophic catarrhal disease with a thickening of the mucous membrane and the submucosa. The glandular elements are markedly hypertrophied. A proctitis of similar nature is likely to be associated. The "iliac roll," "sausage-shaped roll," or "sigmoid sausage," all meaning the characteristic indurated sigmoid, is revealed on examination. This indurated sigmoid is particularly well defined by its peculiar sensitiveness on pressure and also by the effort of the sufferer to push the soreness lower down. The symptoms of mucous colitis, membranous colitis, or chronic colitis may be present, such as painful

crises, constipation, diarrheal attacks, and nervous disturbances. Early morning diarrhea is said by Brunton and Boas to be a characteristic symptom.

Chronic atrophic sigmoiditis is an atrophic catarrhal inflammation with its atrophied glandular elements and a thinning of the mucous membrane. It is always chronic. Its chief symptoms are a prolonged history of constipation and in general those of atrophic colitis. Local manifestations are principally referred to the rectum and anus in the form of hemorrhoids, fissure in ano, and pruritis ani.

Acute perisigmoiditis is suppurative, the clinical picture is one of a collection of pus. There is an elevation of temperature, accompanied by pain, and physical signs of an abscess. The abscess is in the form of a diffuse tumor, irregular in outline, without nodulation, and may be situated, as cited by Maurice Patel, in any of the following positions: "1. Anteroinferior; anteriorly from the iliac spine along Poupart's ligament, intraperitoneal. 2. Anterosuperior; to the left and slightly below the umbilicus, intraperitoneal. 3. Intramesocolic; lying between the two layers of the iliac mesocolon, subperitoneal. 4. Retroiliac; lying between that part of the sigmoid which is covered on its front side with peritoneum and the post-abdominal wall, in the loose tissue. 5. Lumbar abscess: in this variety the pus escapes through Petit's canal and invades the lumbar region."

A perisigmoid abscess perforates some portion of the bowel, as a rule. Peritonitis from this source is generally fatal. There may be a left-sided phlebitis as a result of secondary infection, or a left-sided inflammation of the broad ligament may be associated with this condition.

A true perisigmoiditis may be suspected when, in the female, pelvic inflammations are excluded and a history of enterocolitis exists. We have no pathognomonic symptoms of perisigmoiditis.

Chronic perisigmoiditis is due primarily to some inflammatory process on the outside of the bowel or to an ulcer which has penetrated the coats in which still lingers sufficient irritability to produce an occasional exacerbation. The disease is not limited to the sigmoid alone but extends to the surrounding tissue. The localized pain may help in the diagnosis.

Obstruction due to adhesions to adjacent organs, or to a narrowing of the sigmoid from an exudative process in its outer stricture, is the cause of subjective symptoms.

The treatment of these different affections of the sigmoid is either medical or surgical. The acute catarrhal sigmoiditis must be treated the same as a proctitis of a like nature, that is relieve the cause and use remedies to soothe the inflamed mucous membrane. The remedies most commonly employed for this purpose are solutions of carbolic acid, krameria, nitrate of silver, and flaxseed tea. Opium may be necessary, administered locally. Ice should be applied externally.

Chronic hypertrophic catarrhal sigmoiditis is also subject to the ordinary drugs for hypertrophic catarrhal conditions of the rectum, such as ichthyol, nitrate of silver, and, in general, stimulating remedies. This treatment should be preceded by a generous cleaning out of the intestinal tract with salines to relieve congestion. Atrophic catarrhal sigmoiditis is probably the most intractable of the catarrhal conditions and must always suggest suspicion of syphilis, either inherited or tertiary.

Perisigmoiditis of the suppurative type requires surgical treatment, which should be over the site of the inflammation and earlier than the extension of the inflammation to the peritoneum or a rupture of the abscess.

Chronic perisigmoiditis may be treated locally through a sigmoidoscope or surgically as indications may direct. The origin of the trouble will tend to guide one as to the time and site for operative interference.

THE NARCOTIC METHOD OF TREATING MORPHINISM.*

By CHARLES J. DOUGLAS, M. D.,

DORCHESTER, MASS.

SUPERINTENDENT OF THE DOUGLAS SANATORIUM.

The rapidly increasing prevalence of the morphine addiction, and its disastrous consequences to mind and body, make the study of the best methods for its radical cure of vital and growing importance. Morphinism is far more serious and persistent than any other drug addiction, and if it can be cured with promptness and without pain, a valuable victory for modern therapeutics will have been achieved. Can this be done? I believe we have proved conclusively that it can.

When a morphine patient contemplates taking treatment for his addiction the first question that arises in his mind is: "Will the treatment cause me to suffer?" The withdrawal of morphine from a patient who has habitually used the drug produces great pain and distress, unless ameliorating remedies are employed. Every morphine addict knows this and consequently hesitates to submit himself to any form of treatment that will result in the complete withdrawal of the drug. But if these patients can be assured that it is possible to thoroughly cure them of morphinism without subjecting them to great suffering, the principal barrier to treatment would be removed, and the unfortunate victims of this enslaving drug would gladly avail themselves of such means of emancipation, and be restored to lives of usefulness. To be able to say to such, "You can be cured, and you can be cured without pain," is to bring to these unhappy sufferers a joyful message of deliverance. Morphinism is especially prevalent among intelligent and ambitious people, and to such the bondage is most galling and obnoxious. Yet, struggle as best they can, escape is impossible without medical aid.

There is no disease more surely curable than morphinism. It was formerly supposed, however, that the patient must suffer intensely before a cure could be accomplished. But we have now demonstrated that this suffering can be avoided. Modern medicine has developed a long list of valuable remedies that our ancestors knew not of, and many of these are especially valuable in the treatment of morphinism. If these are properly utilized the morphine patient can be carried from bondage to freedom without passing through the period of pain and general distress that was at one time thought necessary.

Of the various methods of treating morphinism the plan of gradual withdrawal was formerly considered the best. There are, however, several serious objections to it. The patient's suffering is continued over a long period, and the distress of both mind and body gradually increases as the daily allowance of morphine is decreased, and the maxi-

*Read before the American Medical Society for the Study of Alcohol and Narcotics at Chicago, June 3, 1908.

mum of suffering is reached when the last small dose is cut off. A patient using ten grains of morphine daily can easily be cut down to five grains without the aid of remedies, but when the daily allowance has gradually been reduced to one-quarter of a grain, the distress caused by the withdrawal of that small amount will be greater than all the pain caused by the withdrawel of the other nine and three-quarter grains. Another objection to this method is that during the tedious withdrawal period the patient is sorely tempted to use morphine clandestinely, and is pretty sure to do so if he has an opportunity. This of course at once upsets the entire plan of treatment, and it is necessary to begin all over again, only to have the same thing happen a second and third time in many cases. Morphine tablets are so small that they can easily be hidden, and patients who are suffering for the want of the drug, under the gradual withdrawal method, will usually manage to get it in spite of the vigilance of the best nurses. Not only is the temptation great, but the will seems to be temporarily weakened by the morphine, and under such circumstances the patient is not wholly responsible for his acts. It therefore becomes evident that the ideal method of treatment should not only be prompt and painless, but that it should be *sure*.

All these good qualities are found in the plan of treatment which I have named the "Narcotic Method." It is not only painless, but it acts with certainty and precision. There is perhaps no form of human suffering more poignant than that caused by the total and sudden withdrawal of morphine from a morphine habitué. It is comparable to a surgical operation, and my plan is to abolish the pain caused by morphine withdrawal on the same principle that surgical pain is abolished, *i.e.* by keeping the patient either asleep or so thoroughly narcotized during the painful hours that follow the complete withdrawal of morphine that he experiences no suffering. This abolition of pain is the kernel of the whole problem. The patient wants to get rid of morphine as he might want to part with an aching tooth, but he dreads the distress caused by the withdrawal of the drug in the one case, as he dreads the withdrawal of the tooth in the other. I therefore keep him in a somnolent condition till after the painful withdrawal process is accomplished, and then he awakes to the happy realization that while asleep the morphine has been eliminated from his system, the chains have been broken, and once more he is a free man.

No one specific remedy will accomplish this result. A combination of narcotic or hypnotic remedies is necessary, and a dozen different combinations may be required in treating a dozen patients. To enumerate all the remedies that might at times be useful or necessary in the treatment of morphinism would be to name nearly every hypnotic or narcotic remedy in the materia medica, as well as many other remedies not included in these groups. Remedies of this nature often act very differently upon different individuals, and in the treatment of morphinism the physician's armamentarium should include them all. I would, however, warn against the use of hyoscine as a very uncertain and often dangerous drug if exclusively relied upon. Each morphine patient must be studied and treated individually. The principle herein laid down I have, however, found applicable to every case. In the treatment of morphinism by some form of narcotism I have yet to meet my first failure. With a little experience the physician will be able promptly to select the combination of remedies best adapted to the needs of each patient, and thus safely and painlessly withdraw the morphine and restore him to a normal condition.

Physicians who have had little experience in the treatment of morphinism occasionally report remarkable "cures" of this disease. For example, in a recent medical journal a physician reported the case of a woman he treated at her home who had been using morphine in large quantities daily for several years. He reports that he at once stopped the administration of morphine and gave her none throughout the treatment, but administered a few simple remedies. She did not suffer nor crave morphine from first to last, but spent her days in chatting and laughing with her nurse, and her nights in sound sleep. As the remedies he employed could have had no material effect in relieving the great suffering caused by the sudden withdrawal of morphine, there is but one conclusion to be drawn from this report, namely, that the patient had a private supply of morphine and was keeping herself comfortable with it. Of course she did not want her physician to learn that she had deceived him, and it also pleased her to have it announced at the close of treatment that she was cured. In nearly all cases treated at home this will be the outcome. The patient will use morphine clandestinely, in spite of every effort on the part of the attendants to prevent it, and will allow them to think that his comfort and good spirits are due to the wonderful efficiency of the remedies employed. But no one who has had much experience in the treatment of these cases can thus be deceived. There is no specific remedy that will satisfy the agonizing demand for morphine in the nervous system of the addict, while he is attending to his usual business. If he is awake he cannot escape the suffering that invariably results from suddenly stopping the use of the drug, if it has been habitually used for a long time. Sleep is the only remedy, and it is an infallible one. This morphine pain, like surgical pain, can be prevented only on the anesthetic or narcotic principle herein described. In the proper application of this principle will be found a solution of this important problem.

THE EFFECTIVE TREATMENT OF MEMBRANOUS COLITIS.

By DAVID WARK, M.D.,

NEW YORK.

This disease is readily recognized by the following group of well-marked symptoms, a majority of which may be observed in every case:

The sufferers often complain of a feeling of emptiness or faintness in the epigastric region. When this is not caused by hunger it is due probably to exhaustion of the solar plexus. In confirmed cases the whole abdomen is usually tender on pressure, constipation of an obstinate character is the rule, but rarely that alternates with diarrhea. Purgatives may afford temporary relief, but they surely aggravate the disease eventually. Blood in small quantities is often passed with the stools, but more copious hemorrhages rarely occur. Defecation is always accompanied with severe tenesmus so that the sufferer never knows when the act is completed; this symptom is very significant. Pains in the abdomen are sometimes severe, but usually they are merely annoying and irritating. Obstinate insomnia is rarely absent and when sleep does occur it is disturbed by frightful dreams. In every case with-

out exception there is passed with the stools jelly-like matter, with or without shreds of membrane resembling bits of soiled white muslin. In severe cases the whole dejection often consists of this jelly-like and shreddy material; in milder cases it is distributed throughout the stools in masses of varying size, but it is never wholly absent.

The remedy I have used for many years with unfailing success in the cure of membraneous colitis in a large number of cases is the tar yielded by the yellow pine trees (*Pinus palustris*) of Georgia and the Carolinas. It may be prepared by mixing the tar with about an equal weight of wheaten flour, to make a soft mass. Flour is the best excipient because the gluten swells up and absorbs moisture while traversing the alimentary canal, renders the tar more soluble, and therefore more therapeutically effective. The remedy should be put into gelatine capsules No. 2 and the patient should take two or three about one hour after meals. In a few days this treatment, alone, with suitable diet, will cause all the distressing symptoms to undergo very favorable modification. In those cases the tar acts as a most effective and gentle laxative, relieving the constipation remarkably, the quantity of jelly-like matter will be reduced, the stools will assume a more normal appearance and consistence, and the distressing tenesmus will be reduced or quite abolished.

In the more severe cases recovery may often be promoted by the use of high colonic injections of a few ounces of aqua picis given when patients are in the knee-chest position; the liquid thus gravitates far into the diseased colon without the necessity of passing rectal tubes through the sigmoid flexure, which should never be done in this disease. The tar water enema should be given just before the patient retires for the night and should be retained if possible. Static electricity is useful in detecting the location and extent of the disease (which I believe always exists in the descending colon), and is sometimes useful in promoting the removal of the abdominal pains; but the essential remedies are tar and tar water. The diet should be unstimulating, digestible, and nutritious; pepper, hot table sauces like Worchestershire, etc., vinegar, pickles, old, strong cheese, and all alcoholic drinks should be avoided during treatment.

The highly refined tar supplied by the wholesale druggists to retailers is therapeutically inferior in the treatment of this disease to the cruder article sold by ship chandlers for marine purposes. Vegetable tar yielded by the *Pinus palustis* has a very complex constitution and it seems that the steam refining processes to which the former is subjected deprive it of some therapeutic principle. Under the treatment I have noted complete recovery can be confidently expected in from four to six weeks.

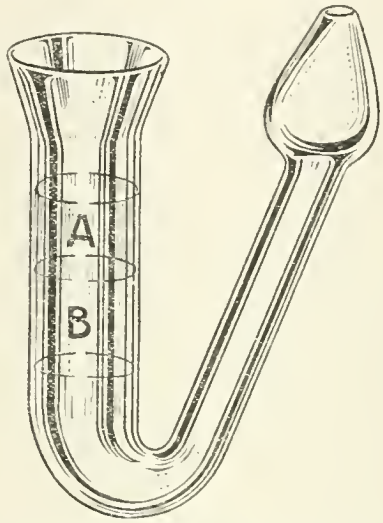
A TUBE FOR SELF-INSUFFLATION OF VAPOR INTO THE MIDDLE EAR.

By PERCY R. WOOD, M.D.,

MARSHALLTOWN, IA.

Catarrhs of the Eustachian tube and tympanum frequently leave in their wake, after every effort to eradicate the etiological factors, a distressing and persistent tinnitus aurium, with progressing deafness. That these sequelæ are often permanently relieved by prolonged inflation of the middle ear with medicated vapors is not generally appreciated, and even when it is, not infrequently treatment cannot be carried out for lack of time or means.

I have devised for home use the instrument here illustrated, consisting of a glass tube bent upon itself, one extremity shaped for insertion into one naris, while the other, retaining the medicament, is held tightly between the lips. When the tube is charged with a small amount of the solution and in place, a sudden expiration drives the vapor directly into the middle ear and adjoining cavities. This treatment restores ventilation, reestablishes



drainage, and vasomotor equilibrium, and so checks sclerotic processes, and if applied persistently for weeks or months, arrests pathological processes of the eustachian tube and intratympanic mucous membrane, relieves tinnitis, and improves audition in a large proportion of cases.

The following solution is serviceable: Chloroform, 120; ether, 60; alcohol, 0.8; oil of rose to scent.

Celery.—According to analysis celery can possess little nutritive value, for over 93 per cent. of the vegetable is water with a little oil, while the balance is made up of some 3.5 per cent. of starchy material, 1.5 per cent. of nitrogenous matters, 1 per cent. of cellular fiber, and 1 per cent. of mineral salts. Celery would, therefore, seem to play almost exclusively the rôle of a condiment rather than that of a food; it is its flavor which makes it popular. There seems to be little doubt, however, that owing to the aromatic oil which it contains celery acts as a mild carminative and stimulant. This property may possibly account for celery eaten raw agreeing very well when taken with cheese. It is well known that the difficulty of digesting cheese occurs in the stomach and that when it is passed into the intestine digestion proceeds as easily and as completely as is the case with meat. Carminatives—as, for example, certain essential oils—favor muscular contraction and therefore favor the continuity of the digestive processes, and there is no reason why the aromatic oil present in celery should not be classed with the carminatives. The oil in celery is allied to the oil of parsley or apiol, which is a well-known carminative, stimulant, and diuretic; celery is further reputed to be "good for rheumatism." In an old recipe occurs the following: "The celery should be cut into bits and boiled in water until soft, and the water should be drunk by the patient. Put new milk with a little flour and nutmeg into a saucepan with the boiled celery, serve it warm with pieces of toast, eat it with potatoes, and the painful ailment will yield." Here we are on less certain ground but at least this procedure amounts to treatment with alkaline salts which so far appears to be rational. Celery contains sodium and potassium salts and also a distinct amount of iron. In spite of the presence of the substances enumerated there can be little doubt that many persons find celery, at any rate if eaten raw, indigestible, which is not surprising when its stringy cellular character is borne in mind. The best celery, of course, is that which is crisp or brittle, but even then there is fiber present which cannot be appropriated by the human organism. Still, the fiber of vegetables serves a useful purpose in promoting a stimulus to intestinal movement.—*The Lancet.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, September 5, 1908.

THE ARMY TEST RIDE IN THE PHILIPPINES.

THERE is a growing apprehension that the army endurance ride, the possible evils of which we have already discussed, will prove even more injurious to many officers weakened by service in the tropics and perhaps cause the retirement of some valuable men whose services the nation can ill afford to lose. The proposition that the officer should lead his horse at a trot for five miles, was wisely omitted from the test, for no matter what a few athletic extremists may say, it is an effort which no man over forty-five or fifty should think of making. But even in its milder form the exertion is too severe, and the results, according to the press reports, are what were predicted: exhaustion, heart failure, or other injury. That nearly all have successfully taken the test so far, merely proves what was already known—any class of men, trained to obey orders at the risk of life, will do so uncomplainingly when the result is nothing more than suffering or loss of health.

The case is different in the Philippines, where the climate causes marked muscular weakness even when proper exercise is taken to the limit of safety. It is said that the death rate among horses has been so large that it is now ordered that they shall not be ridden more than seven miles a day. This exhaustion is so marked in men that it has been found unwise to keep troops there more than two years, and the general trend of opinion among those of experience, is to the effect that not more than one year should elapse before a visit to a cooler climate, if one is compelled by duty to suffer exposure to the sun. Such exertion as riding thirty miles is considered most unwise unless there is necessity. Officers serving in the Philippines are also in no condition to show what their normal endurance really is. It does seem that the interests of the nation demand a postponement of the test until a year or so after return home, if such rides are found to be really necessary. The conditions could be made easier at any rate, though medical science disapproves of the whole matter.

The civilian is somewhat bewildered over all this insistence upon muscular vigor for military commanders, when he reads of Napoleon's habit of reserving his powers for thinking purposes by riding to campaigns in a comfortable carriage. Modern commanders use railroads and automobiles to cover more ground, and only young men in war are ever required to ride a horse thirty miles for three successive days. Unless the public can be convinced of the necessity for these tests, there is likely to be more than indignant protest should serious results happen, particularly in the case of men exhausted by service in Cuba or the Philippines.

THE PATHOLOGY OF MALIGNANT DISEASE.

THE last twenty-five years have witnessed unparalelled progress in the knowledge of the pathology and of treatment of infectious disease: asepsis has greatly diminished the mortality of operations, of accidental wounds, and of child-birth; specific antitoxin has made diphtheria a much less dreaded affection than formerly; quite recently epidemic cerebrospinal meningitis has been successfully treated by a specific serum that has cut down the terrible mortality of this disease. On the other hand, malignant disease, and especially cancer, continues to find its victims in undiminished numbers, various alleged cures being dropped almost as soon as brought forward by some enthusiastic but not judicious physician. In the face of the advance in our knowledge of infectious disease the continued sway of malignant disease seems to call for an explanation for the causes of our ignorance as regards its pathology and treatment, and in a recent publication (*International Clinics*, Vol. II, Eighteenth Series) Dr. Charles E. Simon discusses this question in a very instructive manner. The advance in our knowledge of infections ran parallel to the advance in experimental study of such diseases that became possible with the discovery of specific pathogenic germs and the inoculation of animals with them. Experimental methods, on the other hand, have been applied but very recently to the study of malignant disease, and already our conception of the pathogenesis of tumors has been materially modified by such work, though few practical points as to treatment, beyond the corroboration of the value of early surgical interference, have been obtained.

Of especial value has been the epoch-making work of Jensen who has made the laboratory study of the growth of tumors quite possible by the transplantation of a tumor from mouse to mouse. For five years Jensen's tumor has been growing in transplants throughout the world in striking illustration of that potential power of growth possessed by tumor cells which has led some pathologists to speak of them as immortal in comparison with the human or animal organism which they so readily destroy. Experiments with these transplants have shown that tumors may be carried from one species of animal to another, though to a limited degree; that an epithelial tumor may gradually change into one of connective tissue type through some subtle effect upon the connective tissues of the inoculated animal causing irregular and persistent growth of their elements; that immunization of animals, increasing their resistance to the growth of tumors or even completely abolishing the possibility of engrafting tumors upon their tissues, is possible. Dr. Simon himself has had some encouraging results with the experimental use of cancer extracts in human beings, two cases which he reports in his article having shown remarkable improve-

ment from malignant disease when injections of such extracts were used. Of course he has had many more discouraging experiences, but he shares the opinion of v. Leyden that the few results obtained thus far are full of promise for the future success of artificial immunization against cancer.

Dr. Simon concludes his brief outline of the experimental work in the research of malignant disease and the results obtained, by stating his conviction that this method of study has removed much of the hopeless aspect of the disease, for it has shown that at least some of its manifestations are to a certain extent capable of being influenced by human interference. The lower animals can in a measure be protected against it, and it may be hoped, in view of the analogous cases in infectious diseases, that human beings will soon enjoy the results of the recent experimental study of malignant disease in animals. It must be remembered, however, as a corrective of undue optimism, that so acute an observer and reasoner as Roger Williams denies the identity, even the analogy, of the Jensen tumor with cancer. If he is right, all the experiments with this growth in mice are just so much waste time so far as a clearer knowledge of the nature of cancer in man is concerned. But he may be wrong.

THE DECREASING DEATH RATE OF NEW YORK CITY.

During the summer just passing the weekly reports of the Health Department have shown a very satisfactory state of the health of this city. In the week ending July 25, for example, there were 1,568 deaths, representing an annual death rate of 18.50, while in the same week last year the deaths numbered 1,811, with a death rate of 22.05. The following weeks the deaths were 1,410, with a death rate of 16.63, as compared with 1,804 deaths and a rate of 21.98 for the corresponding week in 1907. For the week ending August 15 there were 1,334 deaths, giving a rate of 15.74, while during the corresponding week of the previous year the figures were 1,656 and 20.16 respectively. This gratifying decrease in mortality, chiefly infant mortality, in spite of the fact that the average of temperature has been higher than that of last summer, has been variously attributed to the improved conditions of living consequent upon the labor of the Tenement-house Commission, to cleaner streets, to the long drought, with its lessened humidity and greater amount of sunshine, to the results of the conference on the Summer Care of Babies held in the spring, to a better milk supply and a more general use of pasteurized milk, to the ever-increasing efficiency of the Health Department, and to other factors making for improved hygienic conditions.

There is one other factor, making not for better health perhaps, but for better mortality figures, which seems to have been overlooked; this is the reduced population of the city. The mortality rates are based upon the estimated population of the city, increasing each year according to a fixed ratio. The present estimate is based upon the figures of the Federal Census of 1900 and the New York State Census of 1905, the assumption being that the same ratio of increase will continue during the years 1905 to 1910 as existed between the years 1900 and 1905. In normal times this would be a conservative estimate of the increment of population since it is ordinarily greater during each quinquennial period than it was during the one immediately preceding. But during the past year there has been a very pronounced disturbance in this ratio, of which the statisticians have not taken account. The business depression of last year threw a great number of persons out of work. Hordes of laborers and others among the foreign population, despairing of finding employment for the present, packed up their belongings and returned to their former homes, where they can live at a fraction of what it costs them to keep body and soul together in this country, and especially in New York City. According to the statistics furnished by the Bureau of Immigration, 572,664 aliens left this country through the port of New York during the eleven months ending May 31, 1908, of which number 109,485 had resided in New York State. It is fair to assume that two-thirds of this number, or 72,990, were from this city. Assuming the same ratio of departures for June, New York City lost 80,134 during the year ending June 30. During the same year 241,343 aliens arrived who gave their destination as New York State, but during the previous fiscal year there were 364,544 arrivals in the State, showing a decrease of 123,201, or 80,134 for the city. This falling off in immigration has been even more marked during the past summer than it was earlier in the year. The total number of aliens arriving in the United States during July of this year was 27,570, against 97,132 in 1907, a decrease of 72 per cent. It is fair to assume, therefore, that, counting the aliens who have gone away and those expected who did not come, New York City to-day has a population at least 175,000 below the estimate of 4,422,685 upon which the calculation of the death rate is based, or more than 40,000 below the estimated population of 1907. That this decrease in population is very real is sadly acknowledged by owners of property in the tenement-house districts on the East Side in Manhattan and elsewhere, where the alien population is greatest.

It must be said, however, that this decrease in population will account for only part of the improvement in the mortality figures. It would make the death rate for the second week of August, for example, about 16.37 instead of 15.74, but that still leaves a decrease of 3.79 per thousand from the rate for the corresponding week in 1907, a decrease which must be credited in very large part to the work inaugurated last spring at the conference for the Summer Care of Babies.

The Effect of Tobacco Smoke Upon Animals.

Innumerable experiments have been performed, designed to demonstrate the toxic effect of tobacco upon the human organism. Usually, however, such experiments have consisted of injections of nicotine or other tobacco elements under the skin or into the blood of animals, procedures which in no way simulated the usual modes of using tobacco peculiar to mankind. Dr. Jebrovsky (*Russkii Vratch*, No.

13, Vol. VII) in some recent experiments has used an ingenious apparatus, by means of which rabbits were kept from six to eight hours daily in a specially constructed chamber, which was filled with tobacco smoke from cigarettes contained in the chamber and "smoked" by means of a draught produced by a water pump. In the first week of the experiments the animals showed increased frequency of respiration, restlessness, and great increase in the secretions of the lacrymal and salivary glands. After "smoking" they appeared weak and apathetic, and dragged their legs somewhat in walking. With the continuation of the experiments those symptoms gradually disappeared, but instead there was noticed marked loss of appetite accompanied by emaciation. Two animals died within two months and the microscopical examination of their hearts showed interesting changes in the nerve ganglia, namely, shrinking of the cells, vacuolization, and some chromatolysis. Other animals killed after five months showed atheromatous changes in the blood-vessels, while great loss of flesh, reaching in some cases one-half of the initial weight, was common to all of them. These experiments led the author to conclude that animals may also become tolerant to the action of tobacco smoke, although this is not the case when tobacco is injected, the resistance of the animals in such cases falling progressively with the continued injections. The pathological changes found bore out the clinically verified assumption that the heart may be early affected by smoking. It is to be hoped that the author will continue his interesting experiments with other animals less sensitive to the toxic effect of tobacco. Meanwhile, the frequent objection of the scoffing devotee of the weed, that medical experiments, as hitherto conducted, merely seem to indicate that tobacco should be smoked and that it is not beneficial to man or beast when injected under the skin, is ruled out by the author's original method of experimentation.

Cytodiagnosis in the Ophthalmo Reaction.

Even before the final value of Calmette's conjunctival reaction in tuberculosis has been settled, various refinements and modifications of the test have appeared in the literature, the general interest in the test having called out a great many articles dealing with the subject. Two French authors have casually examined the secretion produced by the instillation of tuberculin into the conjunctival sac and suggested the value of such procedure. Accordingly, Dr. Rudolph Dietschy has specially examined twenty-eight patients with this point in view and reports his findings in the *Münchener medizinische Wochenschrift* for June 16, 1908. Multinuclear leucocytes predominated during the first few days in the secretion of patients giving a positive ophthalmo-reaction; later lymphocytes prevailed—findings which were quite comparable to those found in the tuberculous inflammations of the pleura and of the meninges. Of special interest were the microscopic examinations in a second series of cases, which gave no positive macroscopic evidence of a reaction; the character of the cellular exudate was such that several cases could be classed as reacting positively, in spite of the absence of gross lesions in the conjunctiva. The author considers that the microscopic appearances of the secretion undergo a series of typical changes, which may be used for the corroboration of a doubtful macroscopic reaction, or even accepted in its place in some cases.

Formalin as a Urinary Preservative.

In consequence of the very complex composition of the urine, holding as it does in solution both organic and inorganic compounds which are subject to organic as well as chemical alterations, this fluid is subject to more or less rapid changes after it has been voided. The rapidity of these changes depends chiefly upon the reaction and concentration of the urine, the temperature at which it is kept, and the degree of access to microorganisms. In cases therefore in which it is necessary to keep urine some time before it can be examined various substances (chloroform, formalin, etc.) are added to preserve it. It is the general belief that these preservatives do not prevent us from ascertaining what the actual constituents of the urine were at the time of voiding. That this is not always the case was shown by Michaud (*Deutsches Archiv für klinische Medizin*, Volume 92, Nos. 3 and 4). He found that diabetic urine containing acetone on being voided, still gave positive acetone tests after standing twenty-four hours or more. If, however, formalin had been added to the urine the acetone tests were negative twenty-four hours later. Quantitative tests showed that this preservative had reduced the total amount of acetone seventy-five per cent. at the end of twenty-four hours. The amount of sugar was not influenced by the formalin. While it is not to be denied that formalin is at times a useful urinary preservative, Michaud's finding should be a warning against its use in all cases, and especially when we wish to ascertain whether acetone is present.

News of the Week.

The Red Cross Tuberculosis Campaign in New York State.—On June 29 the tuberculosis day camp of the American National Red Cross was opened in Schenectady. It is the first of five Red Cross day camps established or to be established this year in America. A Red Cross day camp will be opened in Albany within a short time, and another in New York City on October 1. Other Red Cross day camps are located in Washington, D. C., and Wilmington, Del. The Schenectady camp is located in a pine grove on high flats in the southeastern part of the city. It has two permanent wooden buildings—an office and a kitchen—and on platforms a large dining tent, two hospital tents—one each for men and women—and two conical tents for night campers. Of the medical visiting committee, whose members visit the camp in turn for an hour or two a day, are Drs. C. F. Clowe, H. L. Towne, Peter McPartlon, and J. H. Collins. The camp opened with six patients, and now has fifteen, the probable limit this year. The camp will be open until November 1, and perhaps longer. The design was to take only incipient and moderately advanced cases, but it has been difficult to draw the line in the new undertaking, and the camp has four fairly advanced cases. Several patients sleep in the camp.

The Albany Red Cross day camp, which, it is expected, will open soon under the supervision of the Albany subdivision, will be located on Kenwood Heights on land generously furnished by the Albany Hospital for Incurables. The camp arrangements are in charge of the day camp committee, of which the medical members are Drs. Howard Van Rensselaer, Henry Hun, and Charles K. Winne. The camp's limit this first year will be about fifteen patients. Incipient and moderately advanced cases only will be handled.

The New York City Red Cross day camp will be located on the roof of the Vanderbilt Clinic. The Clinic will fit up the roof at an expense of $10,000, and will supply medical supervision to the camp. The New York County Red Cross will supply nurses, attendants, and nourishment to the forty or more patients to be received. Inasmuch as the Clinic is a member of the Association of the Tuberculosis Clinics of the city, the Red Cross will thus be brought into the organization. The camp will open October 1, and will continue during the day all the year around. After the first few months it is probable that the camp will be open day and night. Medical supervision of the camp will be given by members of the regular staff of the Clinic. The capacity of the camp will be at least forty, and probably more, patients. Incipient and moderately advanced cases will be received, and when the camp is running the twenty-four hours of the day probably more advanced cases can be handled.

The day camp idea is a contribution of the German Red Cross, and was adopted here after investigation and consultation with leading experts and after recommendation to the Red Cross by the National Association for the Study and Prevention of Tuberculosis. The first camp of the kind in this country was opened in Boston some three years ago, and has given such a good account of itself that it has been taken over by the new Consumptives' Hospital in Mattapan. Other camps have also been conducted in Boston, Salem, Mass., Washington, D. C., and in New York City on the disused ferry-boat *Southfield,* conducted last year by the Charity Organization Society and this year by Bellevue Hospital. The day camp has, in fact, come to be recognized as an indispensable part of every progressive plan for the relief and control of tuberculosis.

Pasteurized Milk and the Infant Death Rate.—Mr. Nathan Straus, who has been a year in Europe preaching pasteurization, has had the satisfaction of seeing the practice adopted in many places in Austria, Germany, and England. He was frequently able to demonstrate the beneficial results following pasteurization, but nowhere were his experiments more striking and seemingly conclusive than in Sandhausen, a village of 4,000 inhabitants in South Germany. The death rate among children was very high there, and Mr. Straus was satisfied that this was due to the quality of the milk supply. He therefore made arrangements to pasteurize all the milk supplied to the inhabitants of the village. The experiment began on January 1, and the results have been most encouraging. In the first seven months of 1907 thirty children under one year of age died. In the first seven months of the present year, during which they have been supplied with pasteurized milk, only nine children died.

Giving Up a Half-won Battle.—According to *The New York Times,* the health officer of Newark, N. J., has announced that the board has become so discouraged over the carelessness of the public in not helping to fight the mosquito pest that the city will make no further effort. He declares that the $6,000 spent by the city already is as good as wasted, and that without the hearty cooperation of the public no advance can be made, mosquito-breeding places having been recently discovered in the heart of the city. One who expects to educate the public up to the point of efficient cooperation in sanitary work in one season, or in two, expects too much. Communities are already becoming self-conscious, and it is coming to be regarded as a reproach to any town to be plagued with mosquitos. The Newark people are learning, and their Health Board should not so quickly give up the good fight.

The President on Isthmian Sanitation.—In his letter acknowledging the receipt of a report of the special commission appointed 'to investigate the condition as regards labor and accommodations on the Isthmus of Panama, President Roosevelt expresses satisfaction with all that has been done there, and especially notes the success of Col. Gorgas's work of sanitation. "The treatment of hygienic conditions on the Isthmus," he writes, "has been such as to make it literally the model for all work of the kind in tropical countries. Five years ago the Isthmus of Panama was a by-word for unhealthiness of the most deadly kind. At present the Canal Zone is one of the healthiest places on the globe, and the work which is being prosecuted with such tremendous energy is being prosecuted under conditions so favorable to the health and well-being of the workers that the mortality among them is abnormally small."

Typhoid Fever in New Jersey.—It is reported that typhoid fever prevails to a disquieting extent in Salem, N. J., and in the adjoining section of country in New Jersey and Pennsylvania, and complaint is made that the local health authorities are not doing all they might to prevent the spread of the disease.

Cholera in Poland.—The Asiatic cholera, in its western march across Russia, has reached Lodz, Russian Poland. The German health authorities have increased their watchfulness on the eastern frontier, along which hundreds of medical inspectors have been stationed. They examine all travelers and inspect the river traffic from Russia, quarantining suspected cases. Up to the present time, however, no cases of cholera have been discovered in German territory.

A Test of the Texas Medical Practice Law.—A woman in Bonham, Texas, has brought suit against the State Medical Board to restrain it from interference with her practice of pediatrics and gynecology. The suit is an effort to compel the present board to recognize a certificate issued by an old District Medical Board in 1889 to the applicant and limiting her practice to obstetrics and diseases of women and children. The contention of the attorney-general is that the applicant must confine herself to midwifery or take an examination covering all other subjects if she wishes to practise in diseases of women and children. He also contends that there was no authority in law under the old district régime for issuing a separate license to practise in diseases of women and children, though one for midwifery alone was authorized.

Practising Under a Dead Man's Name.—A man has been arrested in Rochester, N. Y., for the illegal practice of medicine. The man has been practising there for six years, claiming to be a graduate of a New York City medical school. Investigation showed that at the time he said he was studying medicine he was making shoes, and the diploma which he claimed as his own was that of a physician who died in New Jersey.

Tennessee Has No Vital Statistics Law.—Strong efforts will be made by the Tennessee State Board of Health and other organizations and individuals throughout the State to have the next Legislature enact a vital statistics law. The State once had such a law, passed in 1881, but there was much opposition to it, for some reason, and it was re-

pealed in 1883. Ever since that time efforts have been made to have a new law passed providing for the registration of marriages, births, and deaths, but thus far without success.

Marines Treated Prophylactically for Rabies.—An officer and eleven enlisted men of the marine corps, who were bitten by a mad dog in the Panama Canal Zone a few weeks ago and were rushed to the Naval Medical School Hospital in Washington for preventive treatment for hydrophobia, have been discharged. They were at the hospital for twenty-one days. They were bitten at Camp Elliot by the mascot of the camp, which later showed symptoms of rabies.

Pan-American Delegates Plead for Clemency.—A dispatch from Guatamala states that upon the personal request of the delegates from Uruguay, Costa Rica, and Mexico to the Pan-American Medical Congress recently held in that city, President Estrada Cabrera has released the women and political prisoners incarcerated since the attempt was made upon his life.

The Picayune Cup for Public Benefactors.—Mrs. Ida B. Richardson, of New Orleans, has been awarded the Picayune cup, given by a committee of the Progressive Union to the citizen who is thought to have done the most for the public good during the last year. Her latest good work is the erecting of the Medical College Building in memory of her husband and donated to the Tulane Medical College.

Prof. Robert Koch has been the recipient of many honors during his two months' stay in Japan. The government issued official post-cards bearing pictures of the Koch Institute in Berlin and of the Institute for Infectious Diseases in Tokio. Upon his departure for the United States, where he is coming to attend the International Tuberculosis Congress, the Mikado presented him with a magnificent silver tea service.

Charges of Mismanagement Against the San Francisco County Hospital.—The San Francisco Association for the Study and Prevention of Tuberculosis, as the result of a recent investigation, charges that the tuberculous patients in the county hospital at Ingleside are shamefully neglected. In going into details regarding the management of the structure where male patients afflicted with tuberculosis are housed, the committee finds that no careful records of the patients are kept and temperatures are not taken; also, that two of the wards are overcrowded. Hopeful and hopeless cases are indiscriminately placed in the same ward. It is also charged that the patients are inadequately fed, the only addition to the diet given other patients being one raw egg and eight ounces of milk to a patient nightly. No attempt is made to isolate the female patients, they being placed in the general medical female ward. All the tuberculosis patients eat in the general dining-room with the patients from the other departments, thereby rendering the feeble attempt at isolation of the male patients abortive. The dining-room is used as a sitting-room, and the patients huddle in it with tightly closed windows, there being no attempt at ventilation.

Death of M. Becquerel.—The death is announced of Antoine Henri Becquerel, the well-known French scientist, at the age of 57 years. He was professor of physics in the Museum of Natural History, Paris, until 1895, when he was transferred to a similar chair in the Ecole Polytechnique. He was the discoverer of the radiation, resembling in many respects the *x*-rays, from uranium salts, which rays afterward bore his name.

Obituary Notes.—Dr. Stephen Andrew Wood died in Bedford, Mass., on August 12. He was born in Lowell in 1851, and studied medicine first at the New York University Medical School, and later at the University of Vermont, taking his degree from the latter in 1884. He settled immediately in Bedford and had practised there continuously up to the day of his death. He died suddenly of cardiac disease.

Dr. James P. Dunn, of Oakland, Cal., died August 13 in consequence of injuries received in a fall from his horse. He was born in Oakland in 1860 and was graduated from the medical department of the University of California in 1888.

Dr. A. C. Hulbert, of Columbia, Miss., was killed on August 15 by being crushed by the ponderous striking weight of a clock in the court house. He was sitting in the court house just beneath the shaft in which the weights swung.

Dr. C. B. Kennedy, of Parsons, Kan., died suddenly on August 15 of disease of the heart, while attending the funeral of a friend. He was one of the first physicians to locate in Labeth County, and began practice in Parsons over thirty years ago.

Dr. Isaac L. Millspaugh, of Richmond Borough, New York City, died on August 27, after an illness of about six months. He was born in Orange County, N. Y., in 1827, and was a graduate of the College of Physicians and Surgeons in this city in the class of 1850. He was in the medical corps of the U. S. Army during the Civil War. He was a member of the old Richmond County Board of Health, was physician to the New York City Farm Colony, and was a commissioner in lunacy for Richmond.

Dr. Hugh B. McMaster, of Waynesboro, Ga., died at Tryon, N. C., on August 20. He was born in Winnsboro, S. C., in 1856, and was graduated from the Kentucky School of Medicine, Louisville, in 1887.

Dr. Georgiana B. Read, of Providence, R. I., died August 21 of pneumonia. She was born in Providence in 1842, and was graduated from the New York Medical College and Hospital for Women in 1882. For fourteen years she was resident physician at the Moses Brown School in Providence.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MEDICAL SERVICE OF THE NEW TERRITORIAL FORCE—LOWER DEATH RATE—RELATION OF OCCUPATION TO MORTALITY—HEALTH OF PORTSMOUTH—POLLUTED SHELL FISH—SLEEPING SICKNESS—COURT APPOINTMENTS—OBITUARY.

London, August 14, 1908.

The military maneuvers which are being carried out just now, in which regular troops and the new territorial force are engaged, are attracting much attention. Both political parties are now agreed that the Government scheme must have a fair trial and a good deal of patriotism is finding expression, the organization of the medical department of our new army of defense may therefore interest some of your readers. The Director-General, Surgeon-General Alfred Keogh, has issued a report on the subject, from which it appears that the constitution of the Territorial Medical Service is based upon that of the R. A. M. C. and consists of (1) a medical and sanitary service, with combatant units; (2) field medical units, consisting of field ambulance and cavalry ambulances attached to infantry and mounted brigades; (3) sanitary companies; (4) general hospitals. The officers and men are to be distributed among these units. Under the former volunteer system medical officers belonged to combatant battalions in no definitely limited numbers. In the new force units they are limited to war requirements, two to

each unit. But there is further an addition attached to each unit for sanitary work, under the control of the commanding officer, whose responsibility for the prevention of disease is now insisted on. The general hospitals are to receive the sick and wounded from the field army. The Director-General recommends provision for 12,000 beds in twenty-three general hospitals, for which the resources of voluntary aid throughout the country are relied upon. The localities of these are largely determined by the position of great civil hospitals and universities, and twenty-three centers have been selected accordingly. The Director-General is gratified to find that the staffs of these institutions have been ready and anxious to respond to the call for aid in connection with these hospitals. "In no single instance," he says, "in not one of the twenty-three centers has the call been heard without evoking an enthusiasm which in itself is a sufficient indication of the patriotism of the profession to which I belong. It is with no little pride that I am able to announce the approaching enrollment of 368 physicians and 368 surgeons as officers of the Territorial Medical Corps."

He thinks that nurses will volunteer as freely. A matron will be required at each hospital, with thirty sisters and eighty-eight nurses. Every two years she will be given the opportunity of studying for one week the administrative duties of matrons in large military hospitals. As regards voluntary aid societies in the formation of the new general hospitals the British Red Cross Society has already organized itself on a plan similar to the county associations, so that there is a committee in every case to focus county efforts.

The reports of the Registrar-General generally excite a mild interest in the public as well as the profession. Thus expressions of satisfaction are at present common respecting the fall in the death rate which has been general throughout the Kingdom. In the twenty-six great towns the 1907 rate was 15.4 per 1,000 persons living. Bristol had the lowest rate, 13.3, and this is the lowest ever registered.

In the second part of the decennial supplement of the sixty-fifth report, lately published, there is a lengthy statement by Dr. John Tatham on the relation of occupations to mortality, which is getting, as it deserves, considerable attention. It appears that lawyers, both barristers and solicitors, experienced a lower rate of mortality at all ages than the aggregate of males. Law clerks under forty-five years had a lower rate than commercial clerks, but above forty-five the position is reversed. Medical men die faster than lawyers at all stages of life, but compared with the clergy their mortality is enormously in excess. Diseases of the circulatory and respiratory organs are slightly in excess among doctors, while in most other occupations a considerable fall is recorded. Brewers have a low rate under twenty, but above that age a high one. Among publicans the rate is above the standard at every age. Agriculturists under twenty showed a slight excess; at every other age decreased mortality. Among gardeners and farm laborers there were low rates at every age, the lowest being at thirty-five to forty-five years. A difference of 46 per cent. was reported at this age.

The Medical Officer of Health for Portsmouth, Dr. A. M. Fraser, reports the death rate of his borough as 16.02 per 1,000. Referring to diphtheria, 423 cases were notified, equal to 2.0 per 1,000 of the population. He often found the bacillus in the throats of cats, and on inquiry discovered the cat had had a bad cold before the child was attacked. There was an increase of typhoid, 233 cases being notified. Of these, eighty were traced directly to food, viz., contaminated shell fish. "Oysters, cockles, butterfish and mussels are continually picked up from the polluted sources around Portsmouth and consumed with a total disregard to the ill results that are certain to ensue." It seems to Dr. Fraser that the only way to stop this loss of life is by legislation. He would make it illegal to collect shell fish from any place certified by the local Medical Officer of Health to be polluted. As typhoid cases have been reported lately from the same cause in London, we may have more on this matter. Another reckless thing is mentioned by Dr. Fraser. When measles has been in a family the other children have been ordered to attend school by the attendance officer. How is the Medical Officer of Health to restrain the spread of measles in schools if his authority is to be thus superseded?

A dispatch from Uganda reports no new cases of sleeping sickness among Europeans, but during the year 1907 the deaths of natives numbered 12,000. The population has been removed from the shores of the Victoria Nyanza and some thousands of sufferers from the disease are being maintained in segregation camps. It seems evident that the campaign will have to be carried on for years before sleeping sickness is stamped out. Treatment by atoxyl, from which much was hoped, does not seem to have been of great benefit so far.

The vacancies in medical court appointments have been filled as follows: Professor Finlay, M.D., and Professor Sir William Macewen, F.R.S., as honorary physician and surgeon, respectively, to the King in Scotland; Professor James Little, M.D., one of the honorary physicians to His Majesty in Ireland.

It is proposed to raise some memorial of the late Dr. Ashby of Manchester University, who died on the 6th of July. He was long connected with the Liverpool Infirmary for Children, Owens' College and Victoria University. He was a favorite teacher and examiner for many years, and a most skillful physician and most trusted consultant in children's cases.

Dr. Talfourd Jones died on the 29th of July. He was one of Jenner's most distinguished students, but practised for many years in South Wales, where he was the most trusted consultant. He afterwards went to Eastbourne on account of failing health and practised there for several years. Then his health again gave way and he has been an invalid for a long time.

Dr. George Halley, a major in the Third Highland Field Ambulance Corps, was thrown from his horse on the 29th of July and the accident has proved fatal to an officer devoted to the duty and always ready to promote the interests of the service.

Department Inspector-General W. J. Rothe, R.N., retired, died on August 2, aged 74.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

CONGRESS OF GERMAN PHYSICIANS—PROF. LÖBKER'S OPENING SPEECH—RELATIONS OF THE PROFESSION TO THE INDUSTRIAL INSURANCE SOCIETIES—BOYCOTT AT COLOGNE.

BERLIN, July 20, 1908.

THE thirty-sixth annual "Deutsche Aerztetag" annual conference regarding the material interests of German physicians took place this year from June 26 to 29 in the city of Danzig. This meeting represents the whole German medical profession, and its transactions are probably of interest to the foreign colleagues no less than to the German physicians. The opening speech was delivered by Professor Löbker of Bochum; as usual it gave a true picture of the public activities and endeavors of the German profession and we shall attempt to report at least its substance. Dr. Löbker said that the first question on the program referred to school hygiene and to the organization of medical inspectors of schools. Although these questions had a general hygienic interest yet it must not be forgotten that the more narrow matter of the special profession of medicine was very strongly involved in their essence. The matter of a proper reward for the work of physicians in this field of their activity must not be lost sight of. The second point on the program of the Congress had reference to the proposed law dealing with the practice of medicine by irregulars not possessing such privilege from the State, and the sale of secret medicines. Though the projected law was not strong enough or comprehensive enough to drive out the evil completely, for which purpose only the forbidding of all attempts at treatment by unauthorized persons could be sufficient, yet the present meeting is the best assemblage before which the measure can be discussed. Finally, it was necessary to consider the future attitude of the society toward the Union of the German Insurance Societies, who had declared that the various measures proposed by the Congress were completely unacceptable.

The question of a proper attitude toward the medical service in industrial associations has kept the foreground of attention during the past year, and it would seem that the interference of the government with the whole problem will become a necessity in the near future. To understand this matter thoroughly an historical retrospect is necessary. When the law concerning insurance companies, including industrial insurance societies with their medical attendance clauses in case of sickness, was first enacted it included a definition of the duties of the industrial societies toward their members. The lawgivers, however, did not stipulate the reward which the physicians employed by the societies could claim for their services. It seemed to have been the general opinion that the physicians would consider themselves bound by the ethics of their profession to render these services for the least possible reward, the usual membership of the associations consisting of the poorer members of society. This state of affairs did exist for many years, but gradually medical

insurance became so popular that the greater part of the population became entitled to medical attention as members of medical insurance societies, and the whole time and professional skill of a great many physicians had to be given up to such practice among the insured. Soon enough it appeared that the physicians were completely unprotected in their business relations with the associations: the latter dismissed the doctors employed by them on any pretext and at any time; moreover, the services of the physicians were the most important part of the advantages given by the membership in such associations, yet the physicians who furnished these services were not given any voice in the administration of the affairs of the associations. It was then that we began to acquaint the general public with these facts, and in the year 1902 we addressed a letter to the *Reichstag* as well as to the *Bundesrath* recounting the circumstances as they then existed. The address remained without any consequences on that occasion. The next year a project of a new law was placed before the *Reichstag* which had for its object the complete change in the matter of industrial and medical insurance, but that body did not consider that the relation of the physicians to the associations was a proper subject for discussion at the time. The profession then decided to take the matter into their own hands; our Congress issued an open letter to the German physicians in which the latter were urged to defend their interests until the whole question of the relations of physicians to the associations was satisfactorily settled. This appeal had some effect upon the members of the *Reichstag*, and for the first time in the discussions of that body the claims of the physicians to be heard in all deliberations in regard to the proposed changes in the insurance law was regarded as justified. Meanwhile the profession was engaged in organizing itself for the struggle, and in many places the insurance societies were challenged by the organized physicians. One sorry outcome of this struggle was soon apparent; the ranks of the doctors themselves were divided in reference to one important point. Some wanted freedom in the choice of physician, so that the members of the associations could select any physician to treat them that they pleased, while others preferred the older arrangement, under which the association named several physicians to whom the members had to turn when in need of medical attention. It seems self-evident that the latter arrangement gives to the associations all the advantages over the physicians whose appointments and dismissals depended upon the will of the men at the head of the administrations of the societies. Free choice of physicians would seem to be the acceptable alternative for the profession, but opponents to this system were found in the persons of doctors who were already appointed as official physicians of the associations and who feared to lose the advantages enjoyed by them under these arrangements. The greater part of the opponents to the free choice of physicians came from Berlin, but the great body of the profession stood for the right of free choice, and it may be hoped that all medical men will soon unite on this question. The last Congress of German Physicians which took place at Münster had proposed that an audience before the Chancellor be obtained to acquaint him with the wishes of the profession. This audience took place on the 12th of November, 1907, and the Chancellor promised to give his attention to the questions put before him. On the 11th and 12th of June of this year the Chancellor held a conference upon the subject in the Ministry of the Interior and the future relations of the physicians and the insurance associations were considered. In addition to the representatives of the several German states, the administrations of the associations for medical insurance sent their spokesmen to the conference while the medical profession was represented both by the defenders and the opponents of the principle of free choice of physicians. The conference had for its sole object to enable all the interested parties to present thir views to the authorities and therefore no final conclusions were arrived at. However, it may be stated that no future law dealing with the question of insurance societies will be promulgated without calling the medical profession to take part in the deliberations previous to the preparations leading to the enactment of a law on such subject. It remains questionable whether the principle of free choice of physicians will be enacted into a legal right of the members of the associations; our organization must therefore be continued and strengthened so that the discussion of this question as well as of others will find a united and resolute profession behind it.

Once again, too, the Congress of the German Physicians must consider their action in answer to high-handed acts of an administration of a medical insurance society. The present instance of such action has taken place in Cologne where the whole question was fought over four years ago. At that time the result was that the government was compelled to take over into their own hands the administration of the associations in that city. One year ago the right of self-administration was returned to the associations, and ever since the officers have been looking for physicians who would be willing to follow their wishes and demands in every particular. They succeeded, too, in finding several physicians who answered their requirements, but not enough doctors were obtained to cover the demand. We must help the members of the profession in Cologne in their fight for their economic rights, and all members of the profession ought to join the Union of Physicians' Associations which transacts its business at the meeting of the Congress that is opened to-day.

Most enthusiastic applause followed this speech of the Presiding Officer of the Congress. The meeting then proceeded to the transaction of business before it, and we shall report the more important questions considered in our next letter.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 20, 1908.

High-Frequency Electricity in the Treatment of Cardiac Disease.—Horace D. Arnold summarizes his paper as follows: High-frequency electricity may be so applied as to reduce the blood pressure in almost all cases. The amount of the reduction is greater in proportion to the abnormal height of the pressure, although in this series of cases none have been above 200 mm. The greatest fall in the abnormal blood pressure was 40 mm., and the average fall was 17 mm. after an average treatment of twelve minutes. There is good reason to believe that there is also a favorable effect on metabolism and that in this way the conditions that cause the high pressure are improved. For this reason the effect of treatment is not merely temporary, but lasts for a considerable time. This form of treatment will be of special value in cardiac cases where the heart is having difficulty in overcoming high blood pressure, especially where the pressure is due to faulty metabolism or poor elimination. This includes the important class of cardiorenal cases. It will also be useful as an adjunct in the treatment of those cases of high pressure which have not yet developed cardiorenal disease, which are due in part to our strenuous modern competitive life and our excessive ingestion of food.

The High-Grade Mental Defectives.—W. N. Bullard applies the term "higher degree of mental impairment" to those cases in which the defect is least apparent, the so-called border-line cases—those cases which are supposed to stand near or close to the imaginary line which divides the normal from the subnormal or diseased. It is only in a modified way that intellectual ability can be accepted as a satisfactory test for the mental powers. There are other mental qualities which have a large part in the sum of mental characteristics, qualitative and quantitative, which make up the mentality of the normal child. A few of these he mentions. First, there is the moral sense. It is his opinion that the greatest caution should be exercised in placing cases in this category. Secondly, there is a class of persons (girls) who are only slightly weak in power of intellectual acquisition; that is, they can learn a good deal, but they are wholly lacking in practical judgment. Thirdly, there is another class whose difficulty seems to be lack of self-control. They are more or less weak intellectually, but this weakness is not their prominent mental symptom. He believes that it is only in carefully observed cases where some definite intellectual defect exists that they were justified in making a diagnosis of mental irresponsibility. He feels strongly the great danger which exists to society in pushing too far the idea of moral insanity in criminals. Great care should be used in diagnosticating a case as one of moral imbecility. It is only the expert, and the expert in imbecility, not insanity alone, who is fitted to give judgment in these cases. This applies with equal force to those cases in which lack of self-control or of decision seems to be the predominant factor. Girls of the cases described, whether coming from the State school or elsewhere, must be properly provided for and cared for by the State. There is no class of persons in our whole population who, unit for unit, are so dangerous or so expensive to the State; this excepts no class, not even the violently insane. They are dangerous because, being irresponsible wholly or in part, they become the prey of the lower class of vile men and are the most fertile source for the spread of all forms of venereal disease. They have not the sense nor understanding to avoid disease nor any care as to its spread. They are most expensive to the State because they are the most fruitful source of diseased and mentally-defective children, who are apt to become State charges. He does not discuss how these people should be provided for. This properly

comes under the jurisdiction of the State authorities, especially the State Board of Insanity.

New York Medical Journal, August 22, 1908.

Some Important Points in the Anatomy and Surgery of the Peritoneum.—Arthur J. Wolff says that all the splanchnic serosities, distinct in descriptive anatomy, are in reality contiguous diverticula of the same system, the original unity of which is demonstrated by their development. This close embryological relationship is again to be seen in pathology, pathological anatomy, and clinical evolution of the different varieties of pleurisy, pericarditis, and peritonitis. But while the pleura, pericardium, and meninges envelop viscera which are normally aseptic, the peritoneum, on the contrary, covers the most septic of all the organs of the body, the intestines. While the other serous membranes are the most often infected in an indirect manner from the circulatory system, the peritoneum, on the contrary, derives pathogenic agents from the most proximal sources; is infected directly by effraction, contiguity, or continuity, dependent upon the septic organs which it invests. The peritoneal cavity, as well as the pleural, pericardial, and other large serous cavities, is really part of the general lymphatic system, and the serous fluid which at times is found in these cavities is really lymph. The peritoneal surface represents a vast nervous surface, from which any powerful irritation reflects through the sympathetic system upon the cardiopulmonary circulatory system and profoundly disturbs their equilibrium. We have here the explanation of the crises of asystole often observed in the beginning of peritonitis, and also the manifestations of morbid innervation so often seen in these cases; and these grouped together constitute the peritoneal syndrome, as vomiting, constipation, meteorism, pain, tachycardia, alteration of the countenance, of the pulse, etc. It explains also the ensemble of that group of nervous symptoms simulating peritonitis, described under the name of "peritonism." He divides acute peritonitis into two varieties, septic peritonitis, caused by pathogenic microbes, and the second, putrid peritonitis, caused by saprogenetic bacteria. Peritonitis which supervenes as the result of any traumatism, solution of continuity, operative or otherwise, is due to extrinsic infection. The explanation of the variation of the severity of the infectious process may be easily found in the variability of the virulence of the organism producing it. From this argument the surgical treatment of cases of peritonitis is certainly indicated, especially when it is remembered that in general peritonitis medical treatment is of no avail. Avoid too much irrigation in local peritonitis; use systematic and careful irrigation with large quantities of sterile water or normal saline in generalized peritonitis. His experience has led him to adopt this practice and he has had no cause to regret it. He does not believe in the complete closure in all cases of laparatomy. In cases where the drain is used, he allows plenty of water by the mouth. The extensive use of water increases the flow of the liquid through the capillary drain; the flow of lymph is reversed towards the drain, or in the direction of least resistance, the toxins are washed out, diluted, and carried off very promptly. The use of large quantities of water, with good drainage, in these cases, directs the current of serous exudate towards the artificial opening, carrying with it the dead leucocytes laden with dead infectious bacteria, and prevents their being carried through the cellular stomata in the diaphragm and thence into the general circulation.

Oxygen in the Treatment of Tuberculous Peritonitis.—John A. McGlinn says that three types of tuberculous peritonitis are recognized, the ascitic, the fibrous, and the ulcerative forms. Practically all authors are in accord that it is only the first type that is amenable to treatment. In a general way two forms of treatment are recognized, the medical and the surgical. The advantages of surgical treatment have been studied by many writers. From the statement he makes he shows that by the plans of treatment now in vogue the fibrous and ulcerous forms of tuberculous peritonitis are not amenable to treatment, and at best only seventy-five per cent. of the ascitic forms can be cured. It is impossible to devise a scientific form of treatment; therefore, he suggests a plan of treatment which has given him admirable results. He has used the method in fifteen cases; of these four were the fibrous variety. He uses the method as follows: The water bottle of the oxygen apparatus is sterilized and filled with sterile water. The tube leading from the bottle and the rubber tip are sterilized. The tip is covered with several thicknesses of sterile gauze. The oxygen is introduced through the abdominal incision until the abdomen becomes inflated. The incision is now closed with gauze, and the oxygen is allowed to remain for several minutes. The gas is then allowed to escape, and the peritoneal cavity is filled again and again.

The Etiology and Treatment of Eczema.—Zama Feldstein states that eczema forms one-third of all skin diseases that come under treatment. For its production there must be a predisposition or special irritability of the skin; also, an exciting influence which brings this irritability into action. He holds that eczema is a parasitic disease and the only thing necessary to produce an eczema is the condition of the skin. He is of the opinion that the parasite having been once called into activity, as it were, the primary cause can be cured, but the effect, *i.e.* the parasite, remains until destroyed by a parasiticide sufficiently penetrating to establish contact, and sufficiently stimulating to restore the skin to its natural activity. Neisser has stated, "No eczema without micrococci." In the treatment of eczema the following aims should be constantly kept in view: Destroy microorganisms; protect the inflamed surface from further microbic invasion; regulate the strength of the remedy employed to the tolerance of the patient's skin; soothe when acute; stimulate when chronic.

Journal of the American Medical Association, August 22, 1908.

Animal Experimentation.—W. B. Cannon points out how the opponents of physiological experiments assume that all animal experiments must be painful, and discredit, without advancing proof, all statements to the contrary on the part of the investigators. For himself, he can testify that in twelve years' experience as a medical student and physiologist he has never witnessed an experiment of the painful class. On the one side of the controversy, he says, we have men trained to close observation, to careful inference, and to exact statement; on the other side persons revealing repeatedly that they are ignorant of the subject they denounce, that they are incapable of interpreting intelligently what they read, and that they let imagination play uncontrolled in regions and in procedures they have never witnessed. Even the physicians who sign the antivivisectionists' petitions show that they fail to appreciate the worth of research and ignore its direct relations to medical practice. Cannon points out that the antivivisectionists cannot escape profiting by the results of the animal experimentation which they so much oppose, no one in our civilization can avoid such indebtedness. Thousands of useless and harmful animals are annually slaughtered for the public good in our cities, but they object to a few of them being painlessly utilized for the benefit of mankind. We need not question the kindly motives of the opponents of investigation, but they are expending them on animals, while the investigators are working for the good of men.

Suprarenal Transplantation.—F. C. Busch, T. M. Leonard, and T. Wright discuss a new series of thirty cases of suprarenal transplantation. The transplantations were made into the thyroids, testes, and kidneys of dogs and rabbits, not only in the same animal, but also from one animal to another of the same species. The results of implantations into the testes and thyroids were all negative. Positive results were obtained only in those cases in which the kidney was used as a receiving tissue. The experiments in each case consisted of three stages, the technique of which is described. Complete proof of functioning graft survival was obtained in two cases. In one of these the rabbit's suprarenal was transplanted into its own kidney, and thirty-six days later the remaining adrenal was removed. Seventy-seven days after the second operation the kidney containing the graft was removed. In three days the animal died. No evidence of peritonitis and no suprarenal accessories or stump could be found. The second case was that of transplantation of the suprarenal of one rabbit into the kidney of another. The rabbit's remaining suprarenal was removed thirty-six days after the introduction of the graft. The animal recovered. Twenty-nine days later the kidney containing the graft was removed, and the animal died in forty-three hours. From the results of their work the authors conclude that the kidney seems to be the best structure for the reception of the grafts. Whether the graft alone, in any of these cases, would have been sufficient to carry on the suprarenal functions indefinitely the authors cannot say. The longest period of graft survival which they have recorded is 247 days. With improved technique and more uniform success in animal experiments, it does not seem unreasonable to attempt suprarenal transplantations as a therapeutic measure in Addison's disease.

Irregular Hearts.—A. W. Hewlett discusses the subject of absolutely irregular heart action. The most important characteristic is the absence of normal auricular contractions, denoting a fundamental change in the heart activities. It is probably to be interpreted as a total auricular paralysis, or at least as an asthenia of such a grade that the contractions of the auricle are no longer

demonstrable. The mitral stenosis murmur may also disappear, or, if it persists, it loses its presystolic accentuation, which is a fact of diagnostic importance. Physicians should recognize the fact that a typical murmur at such a time is not to be expected. In typical cases of irregular heart the term delirium cordis expresses the extreme lack of rhythm. The absolutely irregular rhythm is one of the most persistent types of arrhythmia, usually lasting till death, though it may be modified temporarily. The heart lesion most frequently present is mitral insufficiency, which occurred alone in ten out of the thirty cases examined, and was associated with mitral stenosis in five more. Rheumatism was the most common antecedent, twelve out of thirty; next came alcoholic excess, very marked in ten. Hyperthyroidism was the only demonstrable cause in two cases, chronic nephritis in one, while arteriosclerosis was noted in a number of others. The symptoms represented every type of heart failure. In some severe types, dyspnea, edema, and effusion into the serous cavities were common. In others the symptoms were less marked, and in two patients no symptoms whatever were complained of. It seems that moderate irregularity with auricular paralysis, especially if valvular disease is lacking, is not enough in itself to cause severe symptoms. The relations to tricuspid insufficiency cannot be exactly defined, but many of these patients have it without doubt, as shown by the typical murmur, the positive plateau on the venous pulse, and the positive pulsations of the liver. Enlargement and tenderness of the liver were present in a large proportion, associated presumably with the tricuspid regurgitation. Delirium cordis may occur in a paroxysmal form, an instance of which is reported, occurring from the excitement of exertion, and associated with auricular paralysis. Probably other factors than merely nervous ones are present in such cases, mitral valve disease existed in the two cases observed by Hewlett. The relation of these paroxysmal cases to the others is probably a near one. He also mentions a form of tachycardia which may also be closely related. In conclusion, he notes the fact that atropine and digitalis produce their well-known effects in these cases of absolute cardiac irregularity, but not to the extent of correcting it.

Weather and Pneumonia.—C. M. Richter discusses the relation of anticyclonic weather to the prevalence of influenza and pneumonia on the northern hemisphere. He deals specially with recent epidemics of pneumonia in Chicago and San Francisco. Because of the small difference between its mean temperature and mean relative humidity of January and July, San Francisco is thought, by the author, to be the best city in the country in which to make research in regard to the influence of weather on disease. The different meteorological factors and the pneumonia mortality figures he charted together for a number of years, and thereby demonstrated that while there was absolutely no relation between temperature and humidity and such mortality, there was a very clear relation between periods of high air pressure and such mortality. He describes the fundamental differences between high and low air pressure—that is, between cyclones and anticyclones. By analyzing the epidemics previously spoken of and studying them with reference to the air pressure prevailing contemporaneously he demonstrates that during a prevalence of anticyclonic weather pneumonia and influenza are generally prevailing. He concludes that: pneumonia is not merely a concomitant of the cold weather season. Its prevalence depends on anticyclonic weather, summer and winter, on the northern hemisphere, and not on low temperature. There is sufficient reason to assume that the quality of the air of an anticyclone changes in conformity with changes in the activity of the sun and that the prevalence of grip and pneumonia is subject to a specific quality of such air.

Experimental Parotitis.—Isabella C. Herb reports experiments on dogs and a monkey by inoculation with the culture of a diplococcus obtained from a man who died from a complication of diseases, including mumps. It was similar in its essential characteristics with that described by Laveran and Catrin and others, and produced when inoculated into Steno's duct of the animals an acute, uniform enlargement of the parotid gland, accompanied with slight fever. In the dog this enlargement is the result of an infiltration that consists largely of mononuclear cells, and is accompanied with a general increase in the mononuclear cells in the blood, as well as a distinct rise in the opsonic index with respect to the diplococcus. Further studies, however, especially of human mumps, are needed before we can say that this diplococcus is the specific cause of mumps.

The Lancet, August 15, 1908.

The Treatment of Immature Cataract.—Henry Smith says that the various procedures for the maturing of immature cataracts are puncturing the lens capsule with a needle: iridectomy (simple): iridectomy with massage through the cornea; and iridectomy with direct massage with some form of instrument. He decides that the extraction of immature cataract by the capsulotomy method is hardly justifiable; that ripening procedures are either unsatisfactory or dangerous; that to wait for nature's maturing process is highly unsatisfactory and detrimental to the patient. The treatment of immature cataract which he practises extensively and which he regards as the procedure of the future, and which will leave mature senile cataract a much rarer condition than it is at present, is extraction of the lens in its capsule, a procedure to which immature cataract is admirably suited. The state of immaturity at which he advocates this procedure is the stage at which it unfits its possessor for the performance of his ordinary duties. His experience now extends to about 20,000 cataract extractions, about 17,000 of which have been in the capsule, and among the latter have been many immature cataracts, especially in recent years.

Note on a Case of Acute Pulmonary Edema.—William Rolland reports the history of a male, 30 years old, who complained of swelling in both legs of six days' duration and of breathlessness. The urine contained a considerable quantity of albumin and numerous casts. The pulse was of high tension. A preliminary diagnosis of subacute or chronic nephritis was therefore made. The patient developed a hacking cough accompanied by slightly sanguineous expectoration and gradually increasing dyspnea. He began to show some lividity and an inhalation of amyl nitrite was administered. The lividity increased to cyanosis, however, and the respiratory embarrassment became extreme. A great quantity of frothy, blood-tinged fluid was coughed up and latterly flowed out of the mouth and nose without expiratory effort. The patient became extremely restless and attempted to get out of bed. He then gradually succumbed to respiratory failure, the heart beating for about one and a half minutes after respiration had ceased. The interval of time between the onset of the cough and the cessation of respiration was about three or four minutes.

British Medical Journal, August 15, 1908.

Pneumonia in Children.—G. H. Melville Dunlop analyzes 500 cases of pneumonia that he has seen in the hospital. Of these 147 were of the lobar variety, the rest of the bronchopneumonia type. Of the 147 cases, 85 occurred in boys, 62 in girls. An immense majority of the cases occurred during the winter and spring months. There were 45 cases under two years of age, 42 between two and five years, and 60 between five and twelve years. The left base was affected in 63 cases, the right base in 25, the right apex in 23, the left apex in 11, both lungs in 8, whole of one lung in 10, and the site not ascertained in 7. The late development of physical signs is of frequent occurrence. The chief symptoms observed heralding the onset of pneumonia were vomiting, headache, pain in the side, shivering, convulsions, and diarrhea. Vomiting in nearly two-thirds of the cases. Pain was more often referred to the abdomen than the thorax. Convulsions do not occur so frequently as an initial symptom as is generally supposed, and very rarely occurred in children over two years old. In none of the 25 cases in which delirium occurred was the child under three years old. Herpes occurred in 11 per cent. of the cases. The crisis took place on the second day in 2 cases; on the third in 3 cases; on the fourth in 6 cases; on the fifth in 16 cases; on the sixth in 15 cases; on the seventh in 16 cases; on the eighth in 22 cases; on the ninth in 14 cases; on the tenth in 10 cases; on the eleventh in 7 cases; on the twelfth in 3 cases; after the twelfth in 6 cases. Of the 147 cases, 24 terminated by lysis. Out of 147 cases, 15 have died, being a mortality of 10.2 per cent. Below the age of two years the prognosis is grave, but above that age it is exceedingly favorable. There were 353 cases of bronchopneumonia, of which 120 were primary and 233 secondary. There were 182 boys and 171 girls. Of the 120 primary cases, 92 occurred in children under two years of age. He was guided in differentiating these cases from lobar pneumonia by (1) the more disseminated character of the lesion in the lung; (2) the remissions in the temperature; (3) the greater amount of cyanosis and dyspnea; (4) the more troublesome character of the cough. In analyzing these 353 cases of bronchopneumonia he finds that both lungs were affected in 182 cases; the right lung alone was affected 83 times, the left alone 72 times, and in 16 the site was not stated. Death was generally due to one or other of the following causes: increasing exhaustion; suffocation and toxemia, owing to the bronchi becoming blocked and the lungs choked; heart failure. He was struck with three points in connection with the cases that terminated fatally: (1) The large number of cases that die very suddenly of heart failure; this occurred in 23 of his cases; (2) the tendency of the temperature to mount higher and higher as death approaches; this oc-

curred 31 times in the 89 cases of death; (3) the great liability of the child to die during an attack of general convulsions, which termination occurred 10 times. The following are the chief points to be considered in estimating the prognosis: 1. The primary disease; those cases which occurred after whooping cough, measles, and diphtheria were exceedingly fatal, giving a death rate of 54.4 per cent. 2. The younger the child the worse the prognosis; 64.4 per cent. of the deaths occurred in children under two years. 3. The greater the extent of the lungs involved the less is the chance of recovery; in 75 per cent. of the deaths both lungs were affected. 4. The poorer the previous health of the child the graver the prognosis. 5. When the child suffers from severe forms of rickets the prognosis is always grave. In 34 per cent. of the deaths the report states that severe rickets existed. 6. Diarrhea seriously affects the prognosis, and was present in 24 per cent. of the deaths. 7. A temperature of 105° F. greatly adds to the gravity of the case; 60 per cent. of these cases died. 8. A pulse rate over 180 and a pulse-respiration ratio of 1 to 2 or 1 to 1-2 is always serious. 9. The highest mortality was in the cases which had lasted for several weeks. The indications for treatment are, first, to endeavor to prevent the digestive organs becoming deranged; second, to do all in your power to maintain the strength and vitality of the patient; third, to keep the action of the heart constantly under observation; fourth, to prevent, if possible, the spread of inflammation to fresh portions of lung.

Zinc Ionization in Chronic Urethritis.—P. Clennell Fenwick says that his attention was drawn to the value of zinc ionization in rodent ulcer by Dr. Lewis Jones some months ago. After using this treatment with success in three cases of rodent ulcer he wondered if the same method could not be used in chronic catarrh of the urethra. He then reports in detail two cases of chronic urethral catarrh of long standing treated by this method with success.

Münchener medizinische Wochenschrift, August 4 *and* 11, 1908.

Artificial Hyperemia in Cerebral Arteriosclerosis.—Galli says that the ultimtae cause of arteriosclerosis is to be found in the degenerative changes of the vasa vasorum or in pathological contractions of their lumina which produce changes in the sections of the vessels that are supplied by the affected arterioles. This explains why the innermost part of the intima is usually the first to suffer from the changes of arteriosclerosis. Artificial hyperemia produces marked changes in the vasa vasorum, and the author tried it for therapeutic purposes in over twenty cases of arteriosclerosis. The elastic tube about the neck is used to produce the hyperemia, the pressure in the tube being controlled by a manometer and raised to from 20 to 50 mm. A daily treatment of one-half to two hours in duration was given. The neurasthenic symptoms which frequently attend this form of arteriosclerosis were very favorably affected by the treatment, and the general wellbeing of the patient soon resulted; advanced cases of arteriosclerosis were not affected. The author warmly recommends the trial of this method of treatment in the early stages of arteriosclerosis affecting the central nervous system.

Nonabsorption of Antitoxin from Rectum.—Hamburger and Monti say that if the absorption of various antitoxins from the rectum could be shown then rectal administration of such substances would be often preferable to subcutaneous injections. Experiments with tetanus antitoxin have shown that very little, if any, of the protective substances found their way out of the rectum into the blood. Of the twenty-four children examined only one gave a positive reaction for the presence of antitoxin in the blood after such administration. Escherich, Pfeiffer, Dehne and Hamburger have obtained similar results with diphtheria antitoxin and with foreign proteids in general. It may be assumed that none of the protective substances in the nature of antitoxins are absorbed by the rectum and, therefore, all good results reported after such administration should be viewed very critically.

The Specificity of Wassermann's Reaction for Syphilis.—Jochmann and Töpfer say that the presence of Wassermann's reaction in such diseases as frambesia does not diminish the value of the reaction as a diagnostic measure because of the extreme rarity of the disease in question in temperate climates. Much and Eichelberg, however, have claimed that scarlet fever patients may give evidence of the reaction and such a finding, if proved correct, would seriously interfere with the usefulness of the Wassermann reaction. The authors have therefore tested the sera of 33 scarlet fever patients in reference to this question and have obtained negative results in 32 cases, one case showing an intermittent positive reaction when larger amounts of serum were used than are required for the diagnosis of syphilitic infection. The method of diagnosing the existence of syphilis devised by Wassermann remains, therefore, quite dependable.

The Treatment of Scarlet Fever.—Oppenheimer says that of his 150 scarlet fever patients he lost only three, and has never observed a case of nephritis. He thinks that the appearance of the latter complication is often due to the use of cold bathing or other extreme hydrotherapeutic measures as well as to the carelessness in the diet of the children. He never uses cold packs or cold baths, making use of compresses in case of headache, unrest, etc. In the diet, meat, meat soups, eggs and even all dishes prepared with eggs are excluded; milk, rice, cooked fruit, a small amount of vegetables, and a little bread make up the diet he has found most efficacious. He admits that the freedom from complications and the low mortality of his cases may be accidental, yet as his method of managing the disease cannot do any possible harm he warmly recommends its trial in other hands.

Granular Form of Tubercle Bacilli.—Wirths says that Much has found in tubercular lesions that were apparently free from bacilli many granular particles which could be stained by Gram's method and which are probably a form assumed by the bacilli of tuberculosis under certain conditions of growth. These granules are often intercellular, lying in the epithelioid or in the giant cells. In several cases of tuberculosis the search for acidfast bacilli was unsuccessful but the granules were found in abundance. The infectivity of the material was proved by inoculation of guinea pigs. The exudate obtained from the inoculated animals contained at first only the granules described by Much and later typical acidfast tubercle bacilli. It seems proved, therefore, that the type stainable by Gram's method alone can pass into the type that may be stained with the usual technique for tubercle bacilli, as for instance by Zichl's method. The opposite metamorphosis has also been observed by the author. He concludes that the granules described by Much are not artefacts nor *débris* of bacilli but virulent organisms that seem to be the most resistant form of tubercle bacilli known.

Deutsche medizinische Wochenschrift, August 6, 1908.

Operative Treatment of Stomach Perforation.—Michelsson says that every case of abdominal injury should be immediately put under the care of a surgeon because perforative and other injuries of the internal organs cannot be readily excluded in the early examination. If a perforation of the gastrointestinal canal is suspected an operation should at once be performed. General narcosis is preferable to lumbar anesthesia in these cases as the upper abdominal organs may have to be handled, which may result in pain and consequent unrest of the patient. The indications to be fulfilled are as follows: The source of infection, if one is found is to be closed; the abdominal cavity is to be cleansed of any infectious material and drainage is to be provided for the exudate that will probably form in consequence of the infection. Such cleansing of the peritoneal cavity is to be done only in cases of spreading peritonitis and large amounts of salt solution are to be used, the washing being continued until the fluid returns clear. Gauze drains are preferable to rubber tubes for drainage. Infusions of salt solution are the best stimulants to the patient in cases of postoperative shock.

French and Italian Journals.

Discontinuance of and Return to a Milk Diet in Diarrheas of Infancy.—Rousseau-Saint-Phillipe says that milk is not the perfect, antitoxic, easily assimilable, complete food that it has been considered. The cow even if healthy, clean, and well fed gives a milk that is not suitable for the child, and it is necessary to watch its digestion and assimilation. When a good, pure milk has been obtained it is necessary to watch its dosage carefully. There are cases both acute and chronic in which it becomes poisonous and excites a gastroenteritis with putrefactions. In these cases milk must be stopped at once and a water diet made use of, with a certain amount of fasting, followed by the use of some other food. When the intestines have been cleansed, disinfected, and returned to a normal condition the use of milk should be begun very gradually and in very small doses, and thus a tolerance be gradually established for it.—*Journal de Médecine de Bordeaux,* May 10, 1908.

Intestinal Occlusion After Gastroenterestomy.—Rigollot-Simonnot says that after any abdominal operation paralytic occlusion without mechanical obstacle, occlusion without by-adhesions, by bands, or by extension of inflammatory lesions or of neoplasms that existed before the operation may occur. In other cases the occlusion results from the technique used in the operation. Three varieties may be distinguished; twisting of the anastomosed gut at

the time of operation or later; fixation of the intestine in the mesocolic breadth of the posterior mesentery and compression of the transverse colon; prevertebral incarceration. Pain is generally present, there is complete suppression of the stools, and of evacuations of gas, vomiting that is frequent, tenacious, and fecal with absence of meteorism. Prophylactic treatment consists in reduction of the afferent loop to the least length that is possible to complete the anastomosis; and closure of any space below the anastomosis by joining the stomach and intestine down to the root of the transverse mesocolon.—*La Tribune Médicale, May* 9, 1908.

Contribution to the Anatomic Pathology of Tumors of the Corpus Callosum.—Giuseppe Panegrossi contributes to the knowledge of tumors of the corpus callosum the following case: A man of fifty-three years of age became rather suddenly confused. He had no history of syphilis, and used wine moderately. Soon after his confusion he fell into a state of stupor in which he remained until his death, about a month later. There were no somatic disturbances at any time. At the autopsy a tumor was found of a gliosarcomatous nature, which had destroyed the anterior two-thirds of the corpus callosum and invaded somewhat the gray and white matter of the median frontal lobes. The points of diagnosis of tumors of the corpus callosum are these: early appearance of mental disturbances associated with disorders of speech differing from aphasia; presence of various motor and topographic disturbances, relating to equilibrium; absence of the general symptoms of intracranial tumors; absence of disturbances of the cranial nerves; subacute onset of the disease and progressive character of the symptoms. Bristow has described a state of stupor or somnolence rendering the patient difficult to nourish and to communicate with.—*Il Policlinico,* May, 1908.

Cases of Otic Pyemia Treated with Antistreptococcus Serum.—Arslan Yervant has made use of antistreptococcus serum in treating otic pyemia. In the case of a girl of twenty years of age after opening of the mastoid up to the aditus there still persisted the symptoms of pyemia. For many days all methods of treatment failed to bring about any improvement. An injection of antistreptococcus serum reduced the temperature in a few hours from 39.5° to 37.5°. After a few more injections the temperature fell to normal. Then the patient was threatened with artrosinovitis with fluctuation and pain. The return to the serum treatment relieved all the symptoms and the temperature fell again to normal. In another subject aged seventy-five years not operated on, the temperature was up to 41.5°, and after the first injection it fell to normal. When serum treatment was suspended complications supervened which caused death. By these cases the antithermic action and the tolerability of the serum is abundantly proven.—*La Riforma Medica,* April 27, 1908.

Treatment of Inguinal Hernia in the Newborn.—Broca says that in considering hernia in young children the degree of malformation is important. Another factor is the influence of rickets on the production of hernia. The obliteration of the peritoneovaginal canal occurs at the moment of the end of pregnancy, and in a premature infant of even fifteen hours there is an incomplete closure, and a predisposition to hernia. Heredity, especially heredity from the father, also plays an important part in these troubles. It is rare to find hernia at the moment of birth, and thus it is not truly congenital. It is frequent to find these herniæ of large size, containing the large intestine, either the cecum or the sigmoid portion. These herniæ also come on slowly, and cough such as occurs in a bronchopneumonia has much to do with the causation. Violent efforts may produce them as well. Diarrhea, and indigestion with colic, and the crying caused thereby are also predisposing causes of hernia. Cure results from the closure of the peritoneovaginal canal. In many cases it is produced in early life by the application of a double bandage, worn day and night, followed at the age of seven to eight months by a suitable truss. This may result in a complete cure in the young infant. Or the hernia may continue to grow larger and give more and more trouble, in which case an operation becomes necessary. The large flaccid stomach and weak abdominal walls of the rachitic child are favorable to this form of hernia. The prognosis of hernia in the baby is very variable. Strangulation occurs rather frequently. A warm bath or mustard paste may cause reduction spontaneously. Severe taxis should never be used, as gangrene may be caused by it. Operation is demanded when reduction is difficult. The child must not be separated from the mother if we wish a baby to live. So the operation should not be done in a hospital that will not admit the mother with the child.—*Bulletin de la Société de l'Internat des Hôpitaux de Paris,* April, 1908.

Surgical Suggestions.

Varicocele.—When operating for varicocele it is far better to make the incision over the external ring, as in herniotomy, than the usual incision in the scrotum. The cord, veins, and artery may be pushed out of the opening, and the veins separated from the others and ligated. The operation is much simpler and easier, involves less laceration and hemorrhage, and the dangers from embolism, thrombosis, and septic infection are greatly minimized. It is wholly unnecessary to touch either the wounds in skin and tunica vaginalis, or the cord and veins—finger infection here being very serious, since the wound must be closed without drainage. It is best sealed with collodion, over which a protective gauze pad should be placed.—*American Journal of Clinical Medicine.*

Everting the Upper Eyelid.—Bishop Harman says that the evertion of the upper lid is one of the simplest and nicest performances when done properly, and should cause no pain to the patient. But, clumsily attempted, it is hard to accomplish, and the bungling causes great pain. The secret of this little maneuvre is to use only the first finger and thumb. Tell the patient to look down; place the inner edge of the thumb parallel with the lower lid, and on its outer half just below the lashes. Place the inner edge of the index finger lightly on the upper lid, just above the lashes, and gently push up the skin; this will cause the edge of the lid to lift from the globe just a little. Now, with the thumb in position, slip the lower lid under the upper lid; and the thumb, following with the lower lid, will get under the upper lid, which can be held firmly betwixt thumb and first finger, and everted, even against a vigorous orbicular spasm. This is the only method which is invariably successful, and, skilfully done, it is painless.—*Clinical Journal.*

Dupuytren's Contraction.—Keen has successfully modified the usual technique employed in the treatment of this affection. The operation was performed under local anesthesia—a few drops of 4 per cent. cocaine solution were injected into the neural sheath. A trapdoor incision, with its base looking toward the wrist, was made; the flap consisted of all the tissues of the palm down to the sheath of the tendons; the entire palmar fascia was then excised. Primary union followed. The results were satisfactory. Keen holds that the technique is especially advantageous in advanced cases where there are distinct bands already formed.—*St. Louis Courier of Medicine.*

Fractures of the Patella.—If it is decided to adopt nonoperative treatment, a satisfactory method is the one known as the "Middlesex method." The limb is put on a back splint until the effusion has subsided. The lower fragment is then fixed by transverse pieces of strapping, which are firmly applied round the joint just below it. The upper fragment is brought down into apposition by strapping over it a piece of adhesive plaster, which is cut away over the patella; to the sides of the adhesive plaster pieces of elastic tubing are attached, which are stretched and fixed to the foot. The two fragments are thus kept more or less in apposition. The apparatus must be retained from six to eight weeks.—*The Hospital.*

The Use of Gloves in Surgery.—In a recent article W. Cohn states that the use of gloves in surgery was first suggested by Halster, who, in 1891, wore sterilized cotton gloves at his operations. Conitzer points out, however, that as long ago as 1855, Thomas Watson, in a work on the practice of medicine, said, in his section on puerperal fever, that it might be possible to invent a glove of some material which should be impervious to fluids but not so thick as to interfere with the sense of the touch, and that if such a glove could be devised it should always be used at every confinement.—*Zentralblatt für Gynäkologie.*

Sprains of the Ankle.—A method of treatment strongly advocated in preference to the usual plan of rest and elevation is that of firmly strapping the part and encouraging the patient to go about as usual, at least after the first twenty-four hours. The strapping is applied so as to enclose the whole foot except the heel; it can be kept on until pain and swelling have subsided, after which, as a rule, no further treatment is required.—*The Hospital.*

Hematuria.—Sir Henry Thompson's method of determining whether blood has come from the bladder or kidneys is to carefully introduce a soft catheter just within the neck of the bladder, draw off the urine and wash out gently with warm water. If the water will not come away clear the blood presumably comes from the bladder. If the water comes away clear, the catheter is then corked for a short while, and the patient kept at rest. When a small quantity of urine has collected it is drawn off and examined for blood. If blood is present, and if, after washing out the bladder, the water comes away clear, the presumption is that the blood comes from the kidney.—*Clinical Review.*

Book Reviews.

A Manual of Venereal Diseases. By Officers of the Royal Army Medical Corps. Introduction by Sir Alfred Keogh, K.C.B., Director-General of the Army Medical Service. History, Statistics, Invaliding, etc., Lieutenant Colonel C. H. Melville, R.A.M.C., Secretary to the Advisory Board. Clinical Pathology and Bacteriology, Colonel Leishman, R.A.M.C. Clinical Course and Treatment, Major C. E. Pollock, R.A.M.C. London (Henry Frowde, Oxford): Hodder & Stoughton (Oxford Medical Publications), 1907.

This manual is intended for officers of the Royal Army Medical Corps and has been compiled by a sub-committee of the Army Medical Advisory Board. It embodies in abstract the recommendations of the Board as to preventive measures. Aside from the fact that the book contains a brief, but satisfactory, summary of the clinical diagnosis of gonorrhea, syphilis, and chancroid, it is of interest inasmuch as it reflects the consensus of opinion of a large number of experienced army surgeons. The "methods of prevention" spoken of consist in disciplinary measures, not in the use of preventive solutions, ointments, etc. For contracting a venereal disease the soldier should be punished, so that his punishment may serve as a warning to others. This method savors of the Orient, and it remains to be seen how it will work.

Dr. Leishman gives an excellent and most complete description of the methods of examining discharges, etc., for gonococci and for spirochæta pallida. Details are given of all the known methods of administering mercury, and preference is given to inunctions and to injections of insoluble compounds, such as the various "creams," which have been popular in the British army for some years past. The question as to the desirability of insoluble as compared to the soluble compounds of mercury has by no means been solved, but preference for the soluble salts in injections is gradually growing stronger, at least in the United States. A series of plans of treatment, with the routine laid down for each period, are also shown in this volume. The appendix contains methods of keeping official histories and records of venereal diseases in the army, a formulary, a number of charts, and statistical tables. The book is to be recommended, especially to army medical officers and to those interested in the comparative study of methods of treating syphilis and gonorrhea.

Diseases of the Nose, Throat and Ear, Medical and Surgical. By William Lincoln Ballenger, M.D., Professor of Otology, Rhinology, and Laryngology, College of Physicians and Surgeons, Department of Medicine, University of Illinois, etc. Illustrated with 471 engravings and plates. Philadelphia and New York: Lea & Febiger, 1908.

In a handsomely printed volume, a bit ponderous to hold with comfort, the well-known Chicago author and clinician presents his views on the allied subjects of diseases of the nose, throat, and ear. He believes that they cannot be considered separately without missing most important connections. Since the well-known two-volume treatise of Bosworth on the nose and throat, which appeared now a considerable number of years ago, no such pretentious treatise has been published in America on the first two divisions of the medical field as that now before us. It covers practically every aspect of the specialties considered, being so well up to date as to have a separate chapter on tracheobronchoscopy and esophagoscopy. The general ground covered is, of course, well suggested by the title, but the author has departed somewhat from the usual methods of presentation, and as a consequence has produced a most readable book. A few matters have, perhaps, been unduly elaborated and some of the illustrations add but little, if any, value to the text. Surgical techniques are clearly elucidated by descriptions of each step of the various operations in numbered paragraphs, and these descriptions are complemented with suitable drawings. Lupus, syphilis, tuberculosis, leprosy, actinomycosis, etc., are grouped under the designation of chronic granulomata. The various statements made on disputed points are so set forth as to express the author's convictions as determined by his own personal experience, and the stamp of sincerity is over all.

We are inclined to question the need of new works of this kind. The vast stream of books on the nose, throat, and ear of the last few years would certainly seem to have filled every demand for literature of this kind in these particular fields. What we need is more careful cultivation of sections of the domain, rather than repetitions of descriptions and diseases as a whole. But we congratulate Dr. Ballenger most heartily on the result of what shows itself to be a most careful work, based on extensive clinical experience. No student who reads this book will fail to be amazed to see how the field of the rhinologist, laryngologist, and otologist has expanded, and no practitioner who looks over it carefully will fail to find many suggestions, the value of which will be attested by his own daily labors.

Treatise on Plague. Dealing with the Historical, Epidemiological, Clinical, Therapeutic, and Preventive Aspects of the Disease. By W. J. Simpson, M.D. Aberd., F.R.C.P. Lond., D.P.H. Camb.; Professor of Hygiene, King's College, London; Lecturer on Tropical Hygiene, London School of Tropical Medicine; formerly Health Officer, Calcutta; Medical Adviser to the Government of Cape Colony during the outbreak of plague in 1901; Commissioner for the Colonial Office to Inquire into the Cause of the Continuance of Plague in Hongkong. Cambridge: University Press, 1905.

The plague was until recently believed to be practically limited to Eastern Asia, but now its prevalence in other parts of the world, and especially on our own Pacific coast, warns us that the disease has no limitations of race or country. As the author says in his preface: "Plague takes its own time and opportunities for its development, and it is unwise to be lulled into a sense of security by its apparent impotency to spread in a particular country. That it is capable of spreading is seen too plainly in India. Few thought it possible, when plague broke out in Bombay in 1896, after an absence of 200 years, that the disease would not be controlled, checked, and stamped out in a short time.

Dr. Simpson divides his book into four parts, dealing with the history and distribution, and the epidemiology of the disease, plague in the individual, and the prevention and suppression of plague. The measures taken to prevent the importation of plague are mentioned, and the author asserts that by a careful examination of rats an outbreak of human plague may be forestalled, by tracing the course of the disease in different localities.

The methods employed for the destruction of rats on board ships are considered, and special attention is given to the Clayton process of disinfecting.

The Operations of General Practice. By Edred M. Corner, M.A., M.C., M.B. (Cantab.), B.Sc. (London), F.R.C.S. (England), Surgeon in Charge of Out-Patients at St. Thomas's Hospital and to the Children's Hospital, Great Ormond Street; Consulting Surgeon to the Wood Green and Purley Hospitals; formerly Erasmus Wilson Lecturer to the Royal College of Surgeons; and H. Irving Pinches, M.A., M.B., B.C. (Cantab.), M.R.C.S., L.R.C.P. (London), Clinical Assistant to the Children's Hospital, Great Ormond Street; late House Surgeon and Obstetric House Physician to St. Thomas's Hospital. London: Henry Frowde, Oxford University Press; Hodder & Stoughton, 1907.

In this work the authors have successfully attempted to meet a deficiency which is perhaps more striking in the English than in the American schools, viz., the practical training in the performance of small and relatively insignificant operations, often lying on the borderland between medicine and surgery. The work is commendable for the terse and systematic manner which the authors have adopted in developing the subject, considering in order the operations of the head, the neck, the chest, the abdomen, the genitourinary apparatus, and, finally, the extremities, respectively.

For reasons of expediency and with a view of keeping within moderate bounds the authors have wisely refrained from discussing alternate methods. This, as they remark in their preface, must of necessity give a somewhat dictatorial character to the book, but at the same time it is a feature that particularly appeals to the average practitioner, clearly differentiating between such cases as should be operated upon and such as are either in the doubtful class or inoperable. The subject matter is presented most attractively and with a striking simplicity of style and diction.

The chapters pertaining to rectal surgery are especially valuable, and there is an excellent, though rather brief, description of Bier's method of passive congestion. The work is freely illustrated and excellently indexed, and will be found especially valuable to the young physician who has not had opportunities for practical work in outpatient dispensaries, and for the general practitioner as a hand-book of ready reference.

Geschichte der Laryngologie in Würzburg. Von Prof. Otto Seifert. Würzburg: Curt Kabitzsch, 1908.

This pamphlet is of interest, especially from a historical point of view. Many names of prominence in the laryngological world have been associated with the institution here described. The contents of the book consist of descriptions of the courses of instruction given, names of principals and assistants, enumeration of cases treated, titles of publications based on this work, etc.

Nothnagel's Practice. Diseases of the Heart. By Prof. Th. v. Jürgensen of Tübingen, Prof. L. v. Schrötter of Vienna, and Prof. L. Krehl of Greifswald. Edited with additions by George Dock, M.D., Professor of Theory and Practice of Medicine and Clinical Medicine, University of Michigan, Ann Arbor. Authorized translation from the German, under the editorial supervision of Alfred Stengel, M.D., Professor of Clinical Medicine in the University of Pennsylvania. Philadelphia and London: W. B. Saunders Company, 1908.

This volume is an admirable successor to those of the series that have preceded it. The important subject to which it is devoted is divided between three authors; Jürgensen having written the first section of 144 pages on cardiac insufficiency, the second of 155 pages on endocarditis, and the third of 100-odd pages on valvular disease. Krehl is the author of the chapters on diseases of the myocardium and nervous diseases of the heart, covering 340 pages, and the volume closes with a section of 66 pages on the diseases of the pericardium by Schrötter. It is unnecessary to say anything in praise of the work of such eminent authorities, and the translation has been done in a manner worthy of the original. The American edition of this large system is now drawing to a close and all those concerned in the long task are to be congratulated on the success with which the difficulties of the work have been overcome.

The Mother's Year Book. Being a Practical Application of the Results of Scientific Child-Study to the Problems of the First Year of Childhood. By Marion Foster Washburne, author of "Family Secrets," etc. New York: The Macmillan Company, 1908.

As a somewhat popular book for the expectant mother, and also for the young mother with her first baby, this volume will serve a useful purpose. It contains much information on the hundred and one little things which interest and appeal to the young mother, and, as a rule, the advice given is healthy. The advice given in the appendix on the Care of the Eyes of the Newborn is not altogether commendable. We think it would be safer for the mother or nurse to call in a physician rather than to decide whether to use boric acid or nitrate of silver.

Febre Amarella. Estudo Clinico com Observaçoes. Pelo Dr. Zeferino Meirelhes, da Academia N. de Medicina do Rio de Janeiro, etc. Rio de Janeiro: H. Garnier, 1907.

The author of this practical manual on yellow fever is physician to the San Sebastiano Hospital and ex-director of the Isolation Hospital of Nitcheroy. He deals with the disease from the viewpoint of wide personal experience. The usual arrangement is followed, the etiology, pathology, diagnosis, and treatment being discussed in turn. The author is very conservative, even skeptical, concerning treatment. Brushing aside any possible specific remedies, he speaks of his sheet anchors in yellow fever—general baths, alkalis (bicarbonate of soda internally and in enemas; alkaline mineral waters), small doses of sulphuric ether (to counteract gastric irritation). Calomel is his favorite intestinal antiseptic and eliminant, while his diuretics are water, milk, and theobromine. The book is a very good one from the clinical viewpoint and is written in simple, direct, and well-ordered style, easily understood, even by those not very familiar with Portuguese.

Traité de L'Arthritisme. Par le Dr. F. Grandmaison. Paris: A. Maloine, 1908.

This treatise on "arthritism" is a very complete and comprehensive presentation of the whole subject, from both the clinical and chemico-physiological viewpoints. The first part deals with the physiology of nutrition; the second with the causes; the third with the clinical manifestation of the disease; the fourth with the complications; the fifth with the evolution, diagnosis, and prognosis, and the last with the treatment of arthritism. The causes of arthritism are discussed under four headings: Heredity, over-eating, sedentary life, nervous over-exertion. In considering the urinary findings in gouty subjects, much attention is paid to quantitative relations of the various solids excreted, and the graphic method is made use of for the purpose of showing abnormalities in excretion. In speaking of the urinary acidity, for example, emphasis is laid upon the fact, brought out by Gautrelet, that there may be either real or potential hyperacidity. Potential hyperacidity is indicated by an increase in total solids as compared with the actual acidity, each reduced to a percentage. In this connection an excess of muscular exercise, etc., will cause real urinary hyperacidity. As regards uric acid in the urine, the author found it generally below normal in quantity in arthritics. It is relatively increased, however, as compared to the total solids. In the chapters on treatment much stress is laid upon physical methods, on diet, exercise, hygienic living, etc., and far less on drugs. The symptomatic treatment is developed along the usual lines, the subject being presented in a clear and attractive manner. There is a tendency towards building hybrid words, such as "dysfonction," "hypodésassimilation," etc., which should be frowned upon, though the intention of the author was simply to coin words that would supplant long phrases.

The book, on the whole, may be compared to the English work of Luff, though it is adapted more especially for general practitioners, and therefore seeks to simplify the more complex modern theoretical and experimental data of the subject of arthritism.

Diseases of the Male Generative Organs. By Edred M. Corner, M.A., M.B., B.Sc., M.C., F.R.C.S., Surgeon to St. Thomas' Hospital, etc., London. (Henry Frowde, Oxford), Hodder & Stoughton (Oxford Medical Publications), 1907.

The title of the book is not quite accurate. It deals with some only of the male generative organs, viz., the testes, spermatic cord, tunica vaginalis, the vesicles, and the scrotum. Nothing is said of diseases of the prostate, and only such conditions of the penis and urethra are mentioned as have to do with the generative function. An attempt has been made, in other words, to discuss separately in this book diseases of the male generative tract as distinct from the urinary tract. What gain such a separation involves is not made clear; indeed, it is most confusing to a student to hunt for a certain disease through various books, only to find that it has been omitted because the authors happened to be interested in a certain line of disorders of a given organ. Those who expect to find something about gonorrhea or syphilis in the present volume, more than the briefest mention, will be disappointed. These are not, it is true, diseases of the generative function, but they certainly affect the generative organs.

Aside from this, the book contains in a very small space a great deal of useful and practical information for students and general practitioners on such subjects as hydrocele, hematocele, undescended testicles, etc. Concise and accurate directions are given for operations and for treatment and much stress is laid upon the differentiation of doubtful conditions. The book is thoroughly up to date and contains the most advanced methods of treatment, *e. g.*, the use of tuberculin in connection with the opsonic index, etc.

The book is written in the informal style of a series of lectures, and embodies chiefly the results of the author's long experience in the out-patient department of the St. Thomas Hospital.

Cosmetic Surgery. The Correction of Featural Imperfections. By Charles C. Miller, M.D. Chicago: Oak Printing Company, 1907.

This is a small book, of about one hundred pages, that deals with the correction of deformities and featural defects of the ears, eyes, nose, and face. Most of the operations described may be performed by any one with a fair knowledge of minor surgery, and they all may be done under local anesthesia.

Abdominal Hernia. Its Diagnosis and Treatment. By W. B. De Garmo, M.D., New York, Professor Special Surgery (Hernia), New York Post-Graduate Medical School and Hospital; Fellow New York Academy of Medicine; Member American Medical Association, New York State and County Medical Societies; Honorary Member of the Medical Society of Virginia. Philadelphia and London: J. B. Lippincott Company, 1907.

Seventeen of the twenty-four chapters of this book are devoted to the consideration of inguinal hernia, in which the surgical care of inguinal hernia in the male and in the female is discussed; the cause of inguinal hernia, its types and conditions, the hernial sac, symptoms and diagnosis, the mechanical treatment, truss fitting, treating by gymnastics, complications in the surgical cure of inguinal hernia, and sigmoid, cecal, and bladder hernia are fully considered. Umbilical and ventral hernias are also treated of at some length. Among the rare forms of hernia are discussed lumbar hernia and the different varieties of sciatic hernia. Dowd's new operation for congenital lumbar hernia is also described. The aim of the author being to provide a book that will be useful to the physician in his work, he has mentioned only those operations which he has found from personal experience to give the best results. This will appeal to the busy man.

The chapter on truss fitting and mechanical and gymnastic treatment will be especially appreciated by the practitioner as a guide in the management of those cases that are either not suitable for operation or in which surgical treatment has been refused.

Society Reports.

AMERICAN NEUROLOGICAL ASSOCIATION.

Thirty-fourth Annual Meeting, Held in Philadelphia, May 20, 21, and 22, 1908.

DR. CHARLES W. BURR, PRESIDENT.

Wednesday, May 20—First Day.

Mental State in Chorea and Choreiform Affections.—Dr. C. W. BURR of Philadelphia presented this, the presidential, address and said that he had chosen this subject because it was of interest in itself and because the study of mental symptoms in physical disease would throw some light upon the nature of the insanities. For example, the study of the mental state in typhoid fever threw some light on the clinical occurrence of delirium. It was unfortunate that the word chorea could not be dropped from use. It included such diverse conditions that it carried with it no clear meaning. Sydenham's chorea was a separate and distinct disease which probably had a specific exciting cause. The majority of patients affected with this disease were entirely sane throughout the course of the disease, although even mild cases showed peevishness, fretfulness, loss of power of attention and selfishness. A second grade showed night terrors and hallucinations; a third, distinct delirium with fever; a fourth, stupor and an acute dementia. Patients of the first and second groups almost always fully recovered; of the third group, frequently died; and of the fourth group, either died or remained demented.

Progressive Hemiplegia Due to Vascular Lesions and a Glioma of the Right Centrum.—Dr. FRANK R. FRY of Cincinnati reported a case of progressive left hemiplegia with the Jacksonian phenomenon but absence of sensory or tumor symptoms. On autopsy there was found a glioma of large size in the right centrum reaching into an immediate subcortical position.

A Case of Cortical Blindness, Exhibiting Apraxic Symptoms.—Dr. JOHN H. W. RHEIN of Philadelphia reported the case of a man of fifty-five years, who had been ill for three years and had developed progressive loss of eyesight together with inability to recognize the position of his body or limbs; loss of the sense of location; loss of tactile and temperature sense in the left hand. Stereognostic perception was impaired on both sides. There was no palsy, but the left hand and arm were contractured and could be moved only reflexly. There was gradual mental failure toward the last and finally death from exhaustion. Autopsy revealed an area of softening in the cortex in the occipitoparietal region on the right side of the brain. Sections showed degeneration in the white matter of both occipital lobes and part of the parietal lobes.

Dr. JOSEPH COLLINS of New York said this patient had once been under his care and that he considered that the case presented all the clinical manifestations of a type of arteriosclerosis which had not been definitely described and which resulted in cerebral softening. He thought the areas of softening described would account for all the objective and subjective signs. He asked whether the autopsy showed arterial lesions and whether serial sections had been made of the brain ganglia and how much degeneration existed.

Dr. ALFRED GORDON of Philadelphia said that in hemiplegia of cortical or subcortical origin there was frequently change of function in the opposite side and asked whether a systematic study of the corpus callosum had been made.

Dr. J. H. W. RHEIN of Philadelphia said, in closing, that there was a general arteriosclerosis. The microscopic lesions of the brain were rather those of perivascular distension and infiltration. This was also present in the white matter, which showed degeneration. The corpus callosum was carefully studied.

Treatment of Facial Spasm by Means of Injections of Alcohol.—Dr. HUGH T. PATRICK of Chicago read this paper, reporting three cases of facial spasm which he had treated by injection of alcohol into the seventh nerve trunk. Two showed good results and in the third there was failure to reach the nerve. Fifteen drops of a 75 per cent. solution of alcohol was injected by means of a hypodermic syringe with a needle of medium length into the trunk of the nerve just in front of the mastoid over the stylomastoid foramen. The nerve was not easy to locate. As soon as the alcohol strikes it, there develops complete facial paralysis which disappears in several months and which is not nearly so annoying to the patient as the spasm. In neither of the author's cases did the spasm return after recovery from the paralysis which resulted from the treatment.

Dr. J. J. PUTNAM of Boston asked whether Dr. Patrick considered that the injection of the alcohol induced a special pathological condition of the nerve and how he explained the result.

Dr. ALFRED GORDON of Philadelphia asked whether the author had had any experience in treating in this way spasms following Bell's palsy.

Dr. H. M. THOMAS of Baltimore asked how long the spasms had existed in Patrick's first case. He had seen a number of cases of operation for facial spasm and thought the palsy which resulted as bad as the spasm. The only case he had seen cured was one of anastomosis with the spinal accessory nerve done by Dr. Cushing. In this case emotional power of motion returned before voluntary power, a phenomenon he could not explain.

Dr. G. L. WALTON of Boston emphasized the presence of other obsessive tendencies in the victims of tic. Sufferers from spasm may be also neurotic, but not necessarily obsessive. He also spoke of the importance of carefully correcting refractive error before resorting to direct attack upon the seventh nerve. He mentioned an obstinate case of many years' standing completely cured by a final adjustment of glasses and muscular exercises for insufficiency.

Dr. CHARLES E. BEEVOR of London, England, asked if there had been any twitching when the needle entered the nerve. He thought, as the nerve was a motor one, there ought to be twitching as soon as the needle entered it.

Dr. RAMSEY HUNT of New York asked if Dr. Patrick had found any etiological factor in these cases. He thought it might be reflex, for in going over the literature he had found that many cases showed some auditory disturbance, aneurysm pressing upon the facial nerve or some such cause. He thought that part of the seventh nerve might be sensory and thus convey the afferent impulses.

Dr. W. G. SPILLER of Philadelphia considered the cases of which Dr. Patrick spoke to be cases of peripheral facial palsy. When regeneration occurred connections of nerve cells took place which were different from those which had previously existed and in this way cells became connected with the upper or lower branches of the facial nerve which had not been in contact before. This accounted for the fact, as noticed, that the facial spasm was always synchronous with closing of the eyelids. He had tested this many times and always found it so.

Dr. J. J. PUTNAM of Boston said he wished to express his acquiescence in what Dr. Spiller had said.

Dr. PATRICK, in closing, said that he did not know how alcohol acted. In answer to Dr. Thomas he stated that his first case of facial spasm had been of ten years' standing. He did not put forward the alcohol treatment as a radical cure nor did he claim originality for it. If spasm returned after the palsy vanished he could see no

objection to repeating the treatment. The muscles did not twitch when the needle was inserted nor was he sure if he had touched the nerve or not. He knew nothing of the etiology in his cases.

A Special Diagnostic Phenomenon in the Attitude of the Head in Cerebellar Diseases.—Dr. Alfred Gordon of Philadelphia presented this communication and said that a certain position of the head in cerebellar disease was not infrequent. Very often the head was inclined towards the side of the lesion. It was of importance when cranial nerve symptoms were absent. The writer had observed in six cases, four of which came to autopsy, the following phenomenon: During the course of the disease and sometimes at the beginning the head had changed its position. Then when it was forcibly turned to its former position, vertigo and pain in the head ensued. The autopsies of Gordon's cases had proved that the phenomenon is of diagnostic value, as when it occurred, it enabled one to determine the seat of the tumor.

Dr. Joseph Collins of New York asked in what way the position of the head described by Dr. Gordon differed from that described by Hughlings Jackson twenty-eight years ago.

Dr. W. C. Krauss of Buffalo said he had seen cases in which this position of the head was present to a remarkable degree.

Dr. M. Allen Starr of New York said that twelve or fourteen years ago he had made a collection of forty cases of cerebellar tumor in order to determine whether the direction of the staggering gave any clue to the side of the tumor. In one-third of the cases the patient staggered toward the side of the tumor and in two-thirds away from the tumor. Since then he had collected others until now he has a series of 100 cases and has come to the conclusion that the direction of staggering gives no clue to the location of the tumor.

Dr. Joseph Fraenkel of New York said that forced movements and forced attitudes of head or extremities were commonly observed in cerebellar disease. The general diagnostic value of these motor phenomena was undisputed and had been frequently described in literature. More debatable, and hardly yet to be used as a guide, was the value of these phenomena as an indication of the exact location of a lesion. The opinions concerning this question to be found in the literature were very contradictory. The physiological literature of this question made statements quite contradictory to those found in the clinical literature.

Dr. Frank R. Fry of Cincinnati said that a few years ago he had reported a case of frontal-lobe tumor which gave all the signs of a cerebellar tumor. He thought the symptoms due to pressure of the cerebellum against the rim of the foramen magnum.

Dr. Philip Coombs Knapp of Boston said that in a good many tumors in different parts of the brain a change in the position of the head would cause increase in dizziness and headache. The head was apt to be turned to the same side as the tumor so as to bring the tumor into the lower portion of the cranial cavity and thus lessen the pressure on other parts of the brain. In cerebellar tumor where ordinarily these symptoms were more marked they would be exaggerated by change in position of the head.

Dr. J. Ramsey Hunt of New York, said he had observed two cases of cerebellar softening in which the head was fixed and he thought this was done to compensate for loss of cerebellar function. He had never been able to determine any fixed position of the head which could be used as a localizing factor.

Dr. Charles E. Beevor of London, Eng., thought the position of the head so very uncertain that it was not of much value for diagnostic purposes. In a very large number of cases there had been no characteristic position of the head.

Dr. John H. W. Rhein of Philadelphia said that the position of the head was not pathognomonic.

Dr. T. H. Weisenburg of Philadelphia said that he has recently collected a number of cases of cerebellar tumor and in most of the cases the cerebellar attitude had been of no value. In two cases there had been diplopia and the patients held their heads in this position to avoid this symptom. When paper was held over their eyes the position of the head was changed.

Dr. Gordon, in closing, said that what he wished to emphasize was that in case of cerebellar tumor the head was first inclined to one side but later inclined to the other side, and that the side to which the head latterly inclined was the side of the tumor.

Two Cases of Aphasia Relieved by Operation, and Their Bearing on Modern Theories of Aphasia.—Dr. B. Sachs of New York presented this paper and said that his first case was a man of thirty-eight who had fallen, striking his head on the right side. Operation had been performed over the site of the fracture but the patient continued unable to talk. The writer had seen the patient five months later and advised operation on the left side. This has been done and a cyst removed from the third frontal convolution. By reeducation the power of talking had been fully restored. The second case was a woman of forty-two who was found suffering from typical sensory aphasia with other evidences of organic brain lesion. Operation was performed in the left temporal region and an abscess found in the temporal lobe. Within a week the aphasia had entirely disappeared. The writer thought that in practice the traditional lines in reference to aphasia should be followed.

Dr. H. H. Hoppe of Cincinnati reported the case of a man who after injury gradually developed parietal sensory aphasia. On operation a small spicule of bone was found under the temporal muscle and around it a cyst pressing upon the temporal lobe. The patient improved after the operation but never completely regained the power of naming objects.

Dr. Joseph Collins of New York said that he considered Dr. Sachs' first case not one of aphasia but one of anarthria. He thought the case a good example in support of Marie's theory.

Dr. Joseph Fraenkel of New York said that Dr. Sachs' first case had been studied by him and it was plainly one of motor aphasia. There was no evidence of paralysis. He thought the case taught that we must still adhere to traditional lines in reference to aphasia.

Dr. Adolph Meyer of New York thought that speaking of points of vulnerability of the speech mechanism and the exact site of speech mechanism were two entirely different things and should not be confounded.

Dr. Sachs, in closing, said that he did not think his cases could be used in illustration of the difference in view between Marie and Déjerine in reference to aphasia and that he did not have that intention in presenting them. He insisted that his first case was one of aphasia and not anarthria, as Dr. Collins claimed.

The Cerebral Arterial Distribution.—Dr. Charles E. Beevor of London, England, presented this paper and related his experience in injecting the various blood-vessels of the brain with soluble colors under uniform pressure and illustrated his results by means of lantern slides. The pressure was maintained by means of pressure bottles, the canulæ entering the various arteries being fed by way of the color bottles from a several-way tube which formed the outlet of the pressure bottle. At various times two, three, four or five of the arteries of supply to the brain had been injected simultaneously. The injections were made in fresh brains which were afterward hardened in formalin. The author had been doing this work for the past six years and had successfully injected and studied about eighty brains.

Dr. M. Allen Starr of New York said that he thought

the members were extremely indebted to Dr. Beevor for his beautiful demonstration and wonderful specimens. A great many of the points, and especially the distribution of the vessels to the internal capsule and the basal ganglia, were quite new to him, and that the work reported should appeal to all as being a very valuable original contribution to the subject.

Dr. H. T. Patrick of Chicago thought one could be impressed to the proper degree with the originality of the idea and the patience and skill required only when he had an opportunity to look over Dr. Beevor's entire collection of brains and see how uniformly successful the results have been.

Dr. J. J. Putnam of Boston asked Dr. Beevor if he had attached any functional significance to this distribution of the vessels.

Dr. Adolph Meyer of New York asked whether any studies had been made in reference to anastomosis of the various arteries and the possibilities of supply in case of occlusion.

Dr. Joseph Collins of New York asked if there was anything in Dr. Beevor's investigation which would indicate the distribution of the end arteries.

Dr. Beevor in closing said he did not think the distribution had any functional significance, but was purely anatomical. In reference to anastomosis and end arteries he said that the basal arteries are certainly end arteries; others are anastomotic. However, there is very little communication between the various branches of the same artery.

The Weight of the Brain as Influenced by Nutrition or Disease.—Dr. H. H. Donaldson of Philadelphia reported his experiments with the brains of white rats and compared these results with those observed in man. It was found that the normal brain weight begins to decrease early in life, in man in the eighteenth or twentieth year. In disease the loss of weight is greater in chronic than in acute diseases. While the loss in weight of the other tissues of man in disease amounted to 24 per cent., that of the brain was only 3 per cent. As a result of improper nutrition in otherwise healthy subjects the brain weight was reduced 4 per cent. There was no loss in the spinal cord in either case.

Dr. J. J. Putnam of Boston asked upon what structures in the brain the loss chiefly fell, whether upon the nerve elements or the myelin sheath.

Dr. B. Sachs of New York asked if the loss in brain weight was greater or less than that of other organs, or whether the brain simply partakes in the general deterioration of nutrition.

Dr. Donaldson, in closing, said that the only element of the loss studied was the amount of water, which was found to be greater in amount in the diseased or poorly nourished brain. He said the whole reason for the inquiry was to show the truth or falsity of the general belief that the brain was unaffected by general disturbance of the body. The loss was more than in the skeleton, but less than in the muscles. No comparisons had been made with other viscera.

Dr. E. C. Spitzka of New York said that in the study of brains of distinguished men allowance had repeatedly been made for a decrease in weight up to 150 grams.

A Brain Tumor Localized and Completely Removed, with Some Discussion of the Symptomatology of Lesions Variously Distributed in the Parietal Lobes.—Drs. Charles K. Mills and Charles H. Frazier of Philadelphia presented this paper, in which they reported the case of a woman, forty-five years of age, in whom the dominating focal symptoms were left lateral homonymous hemianopsia and hemiataxia, the latter especially in the upper extremities. There were slight hyperesthesia, hypasteroeognosis, and hemiparesis. The general symptoms were double optic neuritis, headache, occasional vertigo, nausea, and vomiting. Some mental apathy and marked depression were present. A large parietal osteoplastic flap was raised, and at the upper back part of the opening a large cyst revealed. This was emptied and the entire sac removed. The patient made a good recovery from the operation. All focal symptoms disappeared but the hemianopsia, which was gradually improving. The optic neuritis subsided slowly. It was shown that at least four symptom-complexes useful in guiding operations can be determined in cases of tumor or other lesion of the parietal lobe. The manner in which the focal symptoms and the optic neuritis cleared up after the operation was shown, as was also the importance of rapid one-step operations. The case was regarded as one of radical cure, the microscopic examination showing the cyst removed apparently of a benignant type.

Dr. B. Sachs of New York said that in four cases of his in which the tumor could not be located, as there was no localizing symptom, the optic neuritis had been improved very much by exploratory operation. He believed in exploratory operation in cases where the tumor cannot be localized.

Dr. Charles E. Beevor of London, England, congratulated Drs. Mills and Frazier upon their splendid results. He said he had had a case very much like this one, on which Victor Horsley operated. There was improvement, but the hemianopsia persisted. The difference, he thought, was due to the depth to which the tumor extends. If it extends deeply and destroys the optic radiations there will be no improvement in the hemianopsia.

Dr. J. J. Putnam of Boston reported a case of endothelioma of the cerebellum, operated upon with removal of the tumor, which continued to do well five years after the operation. In a case of hemianopsia in which the tumor was at the base of the brain, involving the fifth nerve on both sides, a decompression operation had given excellent results.

Dr. M. Allen Starr of New York said he was in favor of decompression operation. He had had excellent results in two cases recently. There were cases which result in large hernias and death, but if one in ten could be saved the operation was justifiable. He agreed that brain operations should be done in one stage, and that the surgeon should do everything to hasten the operation and diminish shock.

Dr. Theodore Diller of Pittsburg said that he also was in favor of decompressive operation. He had had a patient recently who showed seven diopters of optic neuritis. Ten days after operation the patient was completely relieved of headache, and although his vision was only 5/200 before the operation he could afterward read a typewritten page.

Dr. Mills, in closing, said that he is in favor of decompressive operation, but that his case was presented, not as one of decompression, but of radical cure.

Dr. Charles H. Frazier of Philadelphia said, in closing, that he quoted the statistics which place the operable tumors at 6 per cent. because he thought that was the opinion of the medical profession, but that in his own experience the operable tumors were 15 to 20 per cent. He believed that if we would explore more routinely we would find the tumor oftener than we do, and that we would find them earlier, and thus get a greater percentage of operability.

Hysterical Insanity, with Report of Some Illustrative Cases.—Drs. Theodore Diller and George J. Wright of Pittsburg presented this paper, and said that hysteria may express itself chiefly by mental symptoms constituting a psychosis which may counterfeit the various other psychoses more or less closely; and this occurs more frequently than is commonly supposed. The recognition of hysterical insanity is important, both from the prognostic and the therapeutic points of view. Inconsequential answers, to which Ganser directed attention, has done much to aid in the diagnosis and to create interest in the

subject of hysterical insanity. Inconsequential and paradoxical conduct are often seen, and are of great diagnostic value. On the negative side hysteria presents a psychosis which does not conform to the pattern of any of the ordinary insanities. The theatrical and dramatic features seen in hysteria generally are to be observed in the hysterical psychoses. Some illustrative cases were given.

Dr. Charles L. Dana of New York said that he had read a great many articles on hysteria, and that every writer had a different conception of it, so that the subject was very puzzling. We could get along much better if the term hysteria was dropped entirely. He did not think we would ever get a clear idea of psychoses so long as we try to establish an hysterical psychosis. He did not say this in criticism of Dr. Diller's paper, which he thought very timely. He said he would like to hear some clear-cut description of this psychosis. He had never seen any clear-cut picture which he could qualify as belonging to this group, although he had seen hysteria combined with some form of insanity.

Dr. Henry R. Stedman of Boston said that if there was such a thing as hysterical psychosis it must be based on physical stigmata. He had met with very few cases of that type, and thought the term hysterical insanity was disappearing from our nomenclature.

Dr. Diller, in closing, said that it was very hard to define insanity, and that he was unable to define hysteria. He thought hysterical insanity was hysteria which presented such profound, prolonged, exaggerated mental symptoms as to constitute the person in the ordinary practical way an insane person.

Thursday, May 21—Second Day.

Localized Epileptic Convulsions Without Gross Lesions of the Cortex of the Brain.—Dr. Herman H. Hoppe of Cincinnati read this paper, confining his remarks to cases showing genuine epileptic convulsions, and did not include those of the Jacksonian, or reflex, type. Only cases in which the physical examination was negative were selected. In one class of cases there developed, without previous epilepsy, a status hemiepilepticus which resulted fatally in a short time. In these cases operation was futile. It was often difficult, even after prolonged observation, to decide whether a given case of localized epileptic seizure was due to an organic lesion or not, as there were so many forms of trauma and disease which might cause an organic lesion. We must, however, conclude that there were cases which were not produced by organic lesion. When the loss of consciousness occurred first and the convulsions followed, and were limited to a small group of muscles, they were undoubtedly epileptic, and not Jacksonian. There was a second class of cases, in which attacks recurred for years and in which there was no progression. The attacks always occurred in the same way. In Jacksonian epilepsy there was steady progression. Differentiation must also be made from hysterical epilepsy.

Dr. L. Pierce Clark of New York said that in a series of eleven cases of status hemiepilepticus at the Craig Colony only one had died. It was not uncommon for cases of this type to go through attacks fifteen times or more. He had looked over the cases Dr. Hoppe mentioned and thought they were not without suspicion or organic lesion. He thought that the underlying lesion in focal epilepsy was a chronic meningoencephalitis.

Dr. F. E. Southard of Boston thought the possibility of a bacterial etiology should be looked into in these cases.

Dr. W. G. Spiller of Philadelphia thought that in cases of doubt as to the presence of an organic lesion operation should be done early, even if it turned out to be only exploratory, for, in case of tumor, success could be assured only by early operation.

Dr. B. Sachs of New York stated that many cases of epilepsy were due to a lesion sustained early in life. That there was some change, either microscopic or macroscopic, we must maintain until there was very strong evidence to the contrary. In a case in which focal epilepsy comes on suddenly in one who has never had epilepsy before, the idea of operation might well be entertained.

Dr. J. J. Putnam of Boston said that, in these cases, while there was no local lesion, there was an area of maximum irritability.

Dr. F. X. Dercum of Philadelphia stated that, in a disease so hopeless as epilepsy, operation should be done if there was only a shadow of a chance of its doing good.

Dr. C. K. Mills of Philadelphia thought the further the question of operation was studied the greater the success. A species of Jacksonian epilepsy sometimes occurred inside the general epileptic attack, and, when this was the case, operation was indicated.

Dr. Hoppe, in closing, said he agreed that microscopic changes could perhaps be found in all cases of so-called idiopathic epilepsy. He believed in operation in the cases Dr. Spiller spoke of, but his cases were not of that kind.

Sane Prototypes of Insane Mental Processes.—Dr. Theodore H. Kellogg of New York, who read this paper, said that insanity was never a spontaneous mental variation, but always evolved on persistent lines of mental action. All insane mental processes had their correlative sane prototypes, which had not been adequately studied. He compared the insane mental processes with their sane prototypes in the following order, viz., delusions of the sane as the casual prototypes of the false beliefs of the insane; extremes of conduct of the insane as uniformly modeled after sane exemplars: insane emotions, propensities, and impulses as directly derived from their sane prototypes; the hallucinations and illusions of the insane as a mere projection of the prototypic sensorial disorders of sanity.

Dr. Henry R. Stedman of Boston said that the only mental conditions it seemed hard to trace were the perversions of instinct, such as sexual perversions and the eating and drinking of loathsome things.

The Course of Sensory Impulses in the Spinal Cord.—Dr. Carl D. Camp of Ann Arbor, who read this paper, said that other sensations than pain and temperature, as first taught by van Gehuchten, were conveyed in the spinal cord by fibers which take their course in different parts of the cord. Pain entered the posterior horn from the posterior root, and ascended in the gray matter for variable distance, varying from two to eight segments, crossed in the posterior commissure, ascended in Gowers' tract to the cerebrum either directly or indirectly. Heat and cold were conveyed by the posterior roots and followed the same course as the pain sense, but were distinct and separate. Tactile sensation passed by the posterior roots up in posterior columns on the same side without decussation. The sense of position came from the joints; motion from the muscles. They entered the posterior horns and ran to the cells in Clark's column, and possibly ascended in the gray matter of the same side for a number of segments, then up in the direct cerebellar tract of the same side.

A Contribution to the Diagnosis of Epilepsy and Dementia Præcox.—Dr. L. Pierce Clark of New York read this paper, and presented the results of a joint study with Dr. E. W. Scripture upon the epileptic voice, in which they had found a characteristic and constant loss of melody. The epileptic speech was "plateau" in form. No other nervous or mental disorder showed the epileptic voice type. The "voice sign" was dependent upon the chronic exhaustion or degeneration of those cortical elements which constitute the brain pathology of epilepsy proper. In three-fourths of all cases of epilepsy one might detect the voice sign without any other knowledge of the disorder being present.

Dr. Clark also showed four colored drawings of the fundus changes found by Dr. Tyson and him in all cases of dementia precox. He laid stress upon the point that one must consider all the signs and symptoms of the eye syndrome to depend upon the syndrome in the prognosis and diagnosis of this psychosis.

A Symptom-Complex of Occlusion of the Posterior Inferior Cerebellar Artery.—Dr. W. G. Spiller of Philadelphia read this paper, and said that the symptom-complex of occlusion of the posterior inferior cerebellar artery was as follows: Sudden onset, usually without disturbance of consciousness; motor power in the limbs and fifth nerve distribution not affected, or at most temporary and slight weakness of the limbs on the side opposite the lesion. Diminution or loss of pain and temperature sensations in the limbs of the side opposite the lesion, and in the fifth nerve distribution on the side of the lesion, or also in the side of the face opposite the lesion; the disturbance of sensation in the face might be only in the first, or first and second branches, or in the whole distribution of the nerve, depending on the upper level of the lesion. Subjective pain, or some form of paresthesia in the area of disturbed objective sensation. Tactile sensation usually intact in all parts. Sense of position usually intact, but sometimes affected. Occasionally a zone of intact sensation in the neck between the zone of disturbed sensation in the limbs of one side and the face of the opposite side. Ataxia in the limbs on the side of the lesion, indicating that the fibers of coordination did not decussate below the medulla oblongata. Tendency to fall toward the side of the lesion; tendency for the head to drop toward the side of the lesion. Nystagmus bilateral, more intense when the eyes were directed toward the side of the lesion. Ménière's symptom-complex; vertigo, revolving vertigo, auditory hallucinations, vomiting; intense headache occasionally. Disturbance of micturition occasionally. Paralysis of the muscles of deglutition on the side of the lesion (vagus), but causing complete inability to swallow, with impaired sensation of the pharynx. Paralysis of the soft palate on the side of the lesion. Paralysis of the larynx on the side of the lesion, voice hoarse, and speaking in a whisper (loss of phonation, with preservation of articulation). Tongue possibly a little weak on the side of the lesion, but the weakness usually not persistent, as the hypoglossus nerve and nucleus usually escaped. Taste lost in anterior two-thirds of tongue occasionally. Paresis of the sixth nerve on the side of the lesion occasionally. Paresis of the facial nerve on the side of the lesion occasionally. The paresis of the sixth and seventh nerves was often absent in a lesion confined to the posterior inferior cerebellar artery, and possibly it might be caused by further extension of the area of softening. Sympathetic disturbance; smallness of pupil, narrowing of palpebral fissure, retraction of eyeball on the side of the lesion. Loss of sweating in the face on the side of lesion occasionally, or increase of sweating in the face on the side opposite the lesion occasionally. Obstinate hiccough. Hemiasynergy on the side of the lesion. Pulse might be rapid from paralysis of the vagus. Loss of tendon reflexes, including the patellar tendon reflex, or in other cases exaggeration of the tendon reflexes. Disturbance of hearing.

Thrombosis of the Posterior Inferior Cerebellar Artery, with Autopsy Revealing the Lesion in the Medulla.—Dr. Henry M. Thomas of Baltimore read this paper, and made further reference to two cases reported in 1896, the second of which ended fatally two and a half years after the onset, but autopsy was refused. A third case was that of a man of fifty-nine, who a week before entering the hospital had intense giddiness, pain in left side of face, difficulty in talking and swallowing, drooping of left eye, and weakness of left face. Examination showed an extremely ill man, with marked vascular, cardiac, and renal involvement. Sensorium dull. Constant hiccough. Left pupil smaller than right. Slight left ptosis. Slight divergent squint of left eye. Dissociated sensory disturbance on left face, right arm, and leg. No sweating of left side of face. Death in four days. Autopsy, among much else, revealed thrombosis of the left posterior cerebellar artery.

Dr. B. Sachs of New York said he had had a patient with unquestionable thrombosis of the inferior cerebellar artery a short time ago, who had practically recovered.

Dr. Theodore Diller of Pittsburg said he had seen three or four cases such as described in these papers.

Dr. Charles E. Beevor of London, England, said he had not come across any case similar to those described.

Dr. D. J. McCarthy of Philadelphia said it should be borne in mind that there was a wide variation in the posterior branches given off by the circle of Willis, hence the symptoms might differ greatly, dependent upon which vessels were involved.

Dr. Spiller, in closing, said the symptom group he described was so striking that, if it was kept in mind, a diagnosis could be made without difficulty.

Dr. Thomas, in closing, agreed with Dr. Spiller, and said that some thirty cases could be collected, both with and without autopsy, showing this sharp cut symptomatology.

Report of a Case of Myasthenia Gravis with Negative Pathological Findings.—Dr. J. Arthur Booth of New York read this paper, and reported the case of a lad of eleven years who presented the familiar symptom-complex of the disease, with a rather acute invasion, following an operation for adenoids. Death from failure of respiratory musculature. Examination of the central nervous system negative and specimens taken from muscles and nerves did not show anything abnormal. Thyroid, parathyroid, and pituitary glands normal. Slight simple hypertrophy of thymus gland.

Dr. N. E. Brill of New York said he regarded the enlargement of the thymus in this case as distinctly pathological. Abnormalities of the thymus occur in 20 per cent. of the cases of myasthenia gravis.

Dr. W. G. Spiller of Philadelphia said he had recently had a case of myasthenia gravis found to be eliminating an excess of calcium chloride in the urine. He was put on calcium chloride, with distinct improvement.

Dr. Booth, in closing, said he did not agree with Dr. Brill that the thymus in his case was pathological.

Rest Treatment in Relation to Psychotherapy.—Dr. S. Weir Mitchell of Philadelphia read this paper, and said that he had invented the rest treatment in 1874, and in 1876 had written a book on the subject, which was soon translated into seven foreign languages. The treatment was not used by others until 1877, when it was administered by Dr. Wm. Goodell. In 1879 it was utilized by Dr. Playfair in England. He had had no reason to complain of the reception of the method of treatment by the profession at large, but many unfair criticisms of it had been made by eminent men, who ought to know better. The good effects were assigned to various influences, some of which did not even form part of the method. Dubois had been an especially unfavorable critic of the Weir Mitchell treatment, a fact which grew out of Dubois' failure properly to understand the method. Dr. Mitchell quoted from this critic's writings to show that his strictures were not warranted. Charcot had claimed priority for isolation, but Dr. Mitchell asserted that he was the first to make use of this measure in the lesser neuroses. The rest treatment was especially adapted to the treatment of neurasthenia, hypochondria, and hysteria. Neurasthenia might be, and often was, a purely physical affection, and psychotherapy would do distinct harm in such cases. Pure hypochrondria was a mental disease, but it was rare. Absolutely nothing was known of hysteria. He believed the clergyman could often give material aid to the physician. Hardly a week

went by that he did not seek the assistance of the clergyman in the treatment of a case. However, no organic disease could ever be relieved by influence exerted upon the mind. Some conditions, as masturbation, irritable temper, and kleptomania were at times favorably influenced by inflicting bodily pain, and Dr. Mitchell sometimes resorted to this measure. Hypnotism was not largely useful in the treatment of disease.

Dr. F. X. Dercum of Philadelphia said the rest treatment was certainly original with Dr. Mitchell, and that the only remarkable fact about the method was that it made use of simple physiological means. The danger in the newer methods of so-called psychotherapy was that they would be used to the neglect of physiological means.

Dr. J. J. Putnam of Boston said that the contribution Dr. Mitchell had made to medicine was a great one, and as complete as Minerva springing from the head of Jupiter. He thought no small factor in Dr. Mitchell's success was his glorious courage and inspiring personality. He agreed with Dr. Mitchell that neurasthenia was often purely physical in nature.

Dr. Charles L. Dana of New York said that Dr. Mitchell's colleagues had never questioned the value of this original contribution to therapeutics. He thought in reference to psychotherapy that it was true that a great many people were going to the wrong place, such as Christian Science and the like, for treatment, and that physicians should acquire a knowledge of all that was good in the way of treatment by whatever name it was called, and be prepared to use it.

Dr. B. Sachs of New York thought that the association should stand in opposition to the psychotherapy idea as recently developed, because it had been horribly overdone, but that physicians should go along as they have always done exerting their influence as physicians, often, perhaps unconsciously, but nevertheless with good effect. He did not think it necessary to coin any new terms.

Dr. Charles E. Beevor of London, England, said he had had in Dr. Mitchell's paper the most delightful treat of his life. He stated that in England the Weir Mitchell treatment was used with the greatest success; also that psychotherapy had not yet invaded the shores of England.

Dr. Philip Coombs Knapp of Boston said he endorsed absolutely everything that Dr. Mitchell had said. The physical condition of the patient was too often overlooked. The most important thing was to put the patient on the best possible physical basis.

Dr. Philip Coombs Knapp of Boston, as chairman of a committee appointed to collect data as to the existence of general paresis and general brain diseases in railway employees, reported that the committee had gone far enough to learn that these diseases were sufficiently prevalent to constitute a grave danger to the traveling public, and that it would be desirable to have locomotive engineers and train dispatchers examined regularly by competent neurologists.

Friday, May 22—Third Day.

The Types of Encephalitis.—Dr. E. E. Southard of Boston read this paper, and considered only the exudative forms of encephalitis, which fall into three groups: (1) Acute, including coccal and typhoid forms; (2) subacute, including tuberculous and luetic forms; (3) the progressive form, or dementia paralytica.

Occupation Neuritis of the Deep Palmar Branch of the Ulnar Nerve. A Well-defined Clinical Type of Occupation Atrophy of the Hand.—Dr. J. Ramsey Hunt of New York read this paper, and said he would isolate a group of occupation palsies of the hand having the following clinical characteristics: (*a*) Atrophic paralysis of the intrinsic muscles of the hand, supplied by the deep palmar branch of the ulnar nerve. (*b*) Reactions of degeneration in the intrinsic muscles of the hand, supplied by the deep palmar branch of the ulnar nerve. (*c*) No objective sensory disturbances of the hand or fingers They were to be regarded as due to compression neuritis of the deep palmar branch of the ulnar nerve as it passed between the muscles of the hypothenar region on its way to the deeper structures in the palm of the hand.

Dr. F. W. Langdon of Cincinnati said the association was much indebted to Dr. Hunt for the way in which he had worked out this form of neuritis. He thought there was a tendency erroneously to ascribe this condition to progressive muscular atrophy.

Dr. Philip Coombs Knapp of Boston said he was very appreciative of Dr. Hunt's careful work, and that his explanation was quite convincing; also that these cases had often been described as beginning spinal myelopathy.

Confusional Insanity and Dementia Præcox.—Dr. Philip Coombs Knapp of Boston read this paper, and stated that too sharp a distinction had been drawn between confusional insanity and dementia præcox, so-called, in the endeavor to establish two distinct diseases. The confusion of the former and the stupor of the latter were only two stages of what was really the same disease. One was a disturbance of projection and the other of perception. The pathogenesis of these conditions had not yet received sufficient study. Intoxication and exhaustion played an important rôle. The so-called dementia præcox was not always precocious, as it might begin after fifty, neither did dementia always occur. Dementia præcox, as a term, characterized the disease too strongly as hopeless, for it was not ordinarily progressive, and was sometimes curable.

Dr. F. W. Langdon of Cincinnati said he agreed with the essayist.

Dr. Alfred Gordon of Philadelphia said we were too ready to jump at a diagnosis of dementia præcox as soon as the patient was found to be a young person.

Facial Paralysis.—Dr. G. A. Waterman of Boston read this paper, which was based upon thirty-three cases of peripheral facial palsy. There was very slight difference in the side or sex affected or in the season of the year. However, exposure to cold and drafts played an undoubted causative rôle; as did also the toxins of syphilis, nephritis, and the like. Ear disease also played a part. The character of pain at the beginning was of no prognostic import.

Prognosis of Spinal-cord Tumors, with Operation.—Dr. William C. Krauss of Buffalo read this paper, and said that the first operative case of spinal cord tumor was that of Gowers and Horsley in 1888. There was one series of 50 cases in the first ten years; a second series of 50 in the next five years, and a third series of 50 cases in the next five years. The prognosis had gradually grown better and better, and was especially good in cysts and sarcoma.

Delayed Apoplexy ("Spätappoplexie") with Report of a Case.—Dr. Alfred R. Allen of Philadelphia read this paper, and concluded that traumatic delayed apoplexy was an entity; that it might be due to an occlusion of the arteries; that when hemorrhage occurred it was not due to necrosis outside of the artery. The artery changes were the result of the trauma.

Officers.—*President,* Dr. S. Weir Mitchell of Philadelphia; *First Vice-President,* Dr. Pearce Bailey of New York; *Second Vice-President,* Dr. F. W. Langdon, Cincinnati; *Secretary and Treasurer,* Dr. Graeme M. Hammond, New York; *Councillors,* Drs. H. M. Thomas of Baltimore and Charles W. Burr of Philadelphia.

The next meeting will be held in New York, the date to be determined by the Council.

Cancer of the Larynx.—There is no part of the body in which cancer occurs which is more favorable for cure than inside the larynx, just as there is no part in which it is less favorable than when it has become extrinsic to the larynx. Hence, there is an urgent appeal for early diagnosis by laryngoscopic examination in cases of hoarseness even when this symptom exists in but a slight degree.—*St. Clair Thomson.*

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, April 20, 1908.

THE PRESIDENT, DR. ROBERT T. MORRIS, IN THE CHAIR.

DR. MAX EINHORN demonstrated an apparatus which simplified the Jacoby-Solms method for the pepsin determination of the stomach contents.

Various Clinical Types of Acute Dilatation of the Stomach.—Dr. ROBERT COLEMAN KEMP stated that one of the main objects of his paper was to emphasize the necessity of a careful examination of the abdomen in all cases, and to demonstrate some of the clinical conditions with which acute dilatation of the stomach might be associated, or in the production of which it might be a prominent factor. It was clearly evident that four anatomical types of this condition existed. 1. Acute dilatation of the stomach alone. 2. Acute dilatation of the stomach supervening upon an existing chronic dilatation (the latter due to stenosis of the pylorus). 3. Acute dilatation of the stomach and duodenum; the most fatal type. 4. Acute dilatation of the stomach and intestines; a mixed type. In discussing the clinical types of acute dilatation of the stomach, Dr. Kemp said that among the symptoms pointing to the nervous system were convulsions in children, epilepsy, migraine, tetany and chorea. Among the cardiac symptoms of which acute dilatation of the stomach was a direct causative agent were the so-called dyspeptic asthma, tachycardia and pseudo-angina pectoris. The effect of the condition on the pulse, respiration and blood pressure were also recognized. In typhoid fever, when distention occurred, it was due to the general systemic infection or else to dietetic errors, and the mixed type, acute dilatation of the stomach and intestine, was quite common. Several fatal cases of the acute gastro-duodenal type had been recorded, but they were rather rare. In the mild cases there was often no vomiting. In acute distention with hemorrhage frequent gastric lavage would relieve the acute dilatation of the stomach and lessen intraabdominal pressure. In pneumonia, Broadbent and Oastler had called attention to the dangers of tympanites, and Holt referred to the danger from dilatation of the stomach in pulmonary disease. The acute gastroduodenal type of dilatation of the stomach had occurred with fatal results on several occasions, with typical symptoms, evidently due to involvement of the vagi during the course of pneumonia. The most frequent type, however, was the mixed type of acute dilatation of the stomach and intestines. The toxins of pneumonia or improper feeding were the chief causes. Acute dilatation of the stomach, Dr. Kemp said, might occur from infancy to old age. Three-fourths of all the severe cases, according to Conner, developed during adolescence or early adult life. It was well, perhaps, to classify the cases as far as possible under the following groups: 1. Cases ascribed to errors in diet. 2. Cases occurring during the active stages of severe infectious diseases. 3. Cases occurring during convalescence from severe or long-continued disease. 4. Cases developing after injury to the head or spine, or after trauma to the abdomen. 5. After operations of all types; abdominal and elsewhere. 6. Cases with other lesions, as with retroperitoneal abscess connected with the duodenum. 7. Cases associated with disease and deformity of the spine. 8. Cases without apparent cause, as after a paroxysm of laughter. The author then described in detail the symptoms and physical signs of acute dilatation of the stomach and intestines, and reported cases illustrative of the various types of the condition.

Perforating Ulcer of the Alimentary Canal.—Dr. H. BEECKMAN DELATOUR reported four cases of this condition. (See page 361.)

Local Treatment of Chronic Diarrhea.—Dr. SAMUEL G. GANT read this paper. He stated that chronic diarrhea was of common occurrence; its progress was insidious and its results were far-reaching. This class of patients not only suffered from exhaustion and loss of weight brought about as a result of the frequent evacuations, but also from nervous phenomena, anemia, skin eruptions, headache, and other manifestations of intestinal autointoxication and underfeeding. In recent years, the author said, he had had unusual opportunities for studying this complaint, and his observations had led him to believe that the primary cause of chronic diarrhea was situated in the colon, and more especially in the sigmoid flexure and rectum very much more frequently than was generally supposed. Colitis was by far the most common cause of this complaint, and it might be catarrhal, tuberculous, dysenteric, syphilitic, or gonorrheal in character. The local treatment of colitis might be non-operative or surgical. Non-operative measures, such as controlling the diet, rest, and colonic irrigations, should be given a fair trial before operative procedures were resorted to. The success of the non-operative treatment depended mainly upon the thoroughness with which the bowel was cleansed. When non-operative treatment failed to cure the diarrhea after a few weeks' or months' trial, one of the surgical operations devised for the relief and cure of ulcerative lesions of the colon should be performed. The following operations had been used with more or less success in the treatment of simple and ulcerative colitis inducing chronic diarrhea: 1. Resection of the colon. 2. Colostomy. 3. Appendicostomy. 4. Cecostomy, with irrigation of the small intestine. Resection of all or a part of the colon was occasionally justifiable in the treatment of colitis, and was indicated when the functionating power of the gut was irretrievably lost as the result of exhaustion, extensive ulceration, cicatrices or multiple polyps. Colostomy had been successfully employed many times in the treatment of chronic diarrhea due to intestinal ulceration, but the procedure had not become popular because of the difficulty experienced in making an artificial anus which would prevent the leakage of gas and feces, and further, because of the danger which accompanied the operation for restoring the continuity of the intestine after the colitis had been cured. Appendicostomy was the most popular of all the surgical procedures which had thus far been devised for the relief and cure of chronic diarrhea. The speaker said that in the *Boston Medical and Surgical Journal* of September 6, 1906, he reported eight cases of chronic diarrhea of different types treated by appendicostomy and through-and-through irrigation, and since that report he had practiced the same method in twenty-seven additional cases of ulcerative colitis. One of his earlier cases died as a result of extensive sloughing of the cecum in the neighborhood of the appendix; in the remaining thirty-four cases, the number of daily stools rapidly diminished immediately following the inauguration of through-and-through irrigation, and the general condition of the patients improved correspondingly. Appendicostomy was not a suitable operation to employ when both an enteritis and an ulcerative colitis were present. Under those conditions he had devised a new and effective way of irrigating the small and large intestine through the same opening, which for the want of a better name he had designated as "cecostomy," with an arrangement for irrigating the small intestine" (Gant's operation). The speaker described in detail the technique of this operation and presented a number of patients upon whom he had operated successfully for the relief of chronic diarrhea, either by this method or by appendicostomy.

Demonstration of a Corset for Visceral Ptoses.—Dr. A. ERNEST GALLANT made this demonstration.

Dr. WILLIAM H. THOMSON said that if we had to deal with an ulcer of the leg and systematically kept on moving it and rubbing it with feces every two or three hours, it was scarcely reasonable to expect that ulcer to heal, and yet that was virtually what happened in the ulcers ac-

companying chronic dysentery. A number of years ago, the speaker said, he recommended that the only rational treatment of this condition was to wash out the gut immediately after each movement of the bowels. For that purpose he used an enema containing the oil of peppermint, and with scarcely any internal medication the method proved much more successful than any hitherto employed. This same principle of treatment was embodied in the surgical method described by Dr. Gant, and it was the only rational treatment of inflammatory or ulcerative lesions of a mucous tract. Several years ago, Dr. Thomson said, Dr. Robert F. Weir came to him with a case of chronic colitis and asked if it would not be a good idea to bring the appendix out of the abdomen, open it, and use it as an avenue or means of entrance for irrigating the lower bowel. He informed Dr. Weir that he was delighted to hear that the appendix was at last to be turned to some good use, and experience showed that such proved to be the case. The intestinal tract was the great channel of autoinfection of the human race, and the speaker said he was entirely willing to leave these cases of chronic dysentery in the surgeon's hands. In discussing Dr. Kemp's paper, Dr. Thomson, after referring to the important rôle played by the sympathetic as the third great nervous system, said that when tympanites occurred in the course of any infectious disease, it was always of ominous significance as an indication of a toxemia that was producing very serious vital prostration. In pneumonia, for example, acute dilatation of the stomach was a very serious sign; it pointed to an intense toxemia, and the prognosis in such a case could not be based merely upon the extent of the consolidation of the lung, but account must also be taken of the pronounced depression of the vital forces.

Dr. Max Einhorn said the frequency of so-called dilatation of the stomach depended largely on what we understood by that term. If we included under it a slight increase in the size of the stomach, then such a condition was very frequent. Personally, he would classify these cases of temporary and comparatively slight increase under the term of atony of the stomach. At all events, the mere size of the organ was of secondary importance as compared with the actual symptoms. If there was vomiting and abdominal distension, and the stomach did not propel its contents properly, then we had a condition of real interference with the motility of the stomach, dependent on a morbid process. In acute diseases, such as pneumonia and typhoid fever, it should be remembered that the tympanites that might occur was dependent on another symptom-complex and it could not, therefore, be classified as acute dilatation.

Dr. Joseph Merzbach said that acute dilatation of the stomach was by no means a rare condition, and it was certainly more frequently overlooked than recognized. He referred particularly to two kinds of gastric dilatation: 1. Postoperative acute dilatation. 2. The acute dilatation which occurred accompanying pyloric stenosis in infants. Both of these forms were frequently unrecognized. Dr. Merzbach said the four cases reported by Dr. Delatour were very interesting and illustrated the difficulties of making a correct diagnosis of intraabdominal conditions prior to operation. In two of his cases the perforation had occurred without any premonitory symptoms whatever. The surgical results in these cases were certainly encouraging, and if such a patient recovered without surgical interference, as occasionally occurred, it should be regarded as nothing but a lucky accident, and not the normal result of expectant treatment.

Dr. Jacob Kaufmann said he agreed with Dr. Einhorn that some of the conditions described by Dr. Kemp should not be classed as acute dilatation of the stomach. On the other hand, atonic dilatation was of frequent occurrence and was often overlooked, especially when it was postoperative. This was perhaps due to the fact that in many instances in which there was paralysis of the stomach, belching and vomiting were both absent, and this allayed suspicion. In discussing the etiology of acute dilatation of the stomach, Dr. Kaufmann said that from his own observation and from a study of the literature, especially the writings of Braun and Seidel, he was not inclined to accept the theory that mechanical factors, such as pressure of the mesentery on the third part of the duodenum, played any great rôle in its production. Just as in certain infectious diseases the dilatation was one of the manifestations of toxemia, so in the postoperative type he was inclined to attribute it to the effects of the narcosis on the center regulating the motor activity of the stomach. There was another type of acute dilatation of the stomach occurring in persons apparently perfectly well which was brought about by the ingestion of large quantities of easily fermentable substances; this type was first described by Naunyn about a quarter of a century ago. There was no doubt that acute dilatation of the stomach, occurring in the course of an acute disease or as a postoperative complication, was a very serious condition. The most effective method of treatment was to immediately evacuate the stomach by lavage, even in the face of gastric hemorrhage.

Dr. Nathan L. Bodkin said that Dr. Gant's title of Surgical Treatment of Chronic Diarrhea was in his opinion too vague to warrant an operation for all cases of chronic diarrhea, classifying them under one head, as Dr. Gant had certainly cured many cases with medical treatment. In the simple catarrhal type of chronic diarrhea, meaning mucous colitis, chronic colitis, or catarrhal colitis, non-surgical methods of treatment were oftentimes entirely effective when the primary cause was removed, while in dysentery of the amebic, bacillary, or mixed type of infection a more radical method, such as Dr. Gant had described, was often absolutely necessary. The time might come when the surgeon would be consulted by the dermatologist for such a method of irrigating the bowel in cases of pemphigus and erythema multiforme of the severe and recurrent type, which were probably the result of autointoxication. Personally, the speaker said, he had seen a few cases which were undoubtedly of intestinal origin. In cases where the trouble was confined to the sigmoid, treatment could be instituted from below with the aid of the sigmoidoscope. The method of irrigating the small and large intestine by introducing the catheters through the incision in the cecum was a good one, but the question as to whether there would be a reverse peristalsis and the distance the fluid might be introduced seemed one which Dr. Gant alone could explain. The idea of putting a purse-string suture about the valve, tying in the catheters, instead of the ordinary Gibson valvular colostomy method, anyone might appreciate who had inverted an appendix.

Dr. Ludwig W. Kast said that a sufficiently clear distinction had not been drawn between symptomatic enlargement of the stomach and acute dilatation. What appeared at times to be an acute dilatation might prove to be due to actual motor insufficiency. In discussing Dr. Gant's paper, the speaker said that those cases of chronic diarrhea dependent on ulcerations in the rectum and sigmoid flexure were much more amenable to local treatment through the rectum than were those in which the condition was due to disease of the cecum. The great majority of these patients could be benefited by simple irrigations through the rectum as long as the condition that gave rise to the trouble was reachable. In this connection, he called attention to the so-called "dry treatment" followed at Rosenheim's clinic, which consisted in introducing the sigmoidoscope as high up as possible, and then applying silver nitrate or various powders directly to the surface of the ulcer.

The discussion was continued by Dr. MacEvitt and was then closed by Drs. Kemp, Gant and Gallant.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE BOOK OF PRESCRIPTIONS (BEASLEY). By E. W. LUCAS, F.I.C., F.C.S. 16mo, 366 pages. Cloth, $2.00 net. P. Blakiston's Son & Co., Philadelphia.

A TEXT-BOOK OF HUMAN PHYSIOLOGY. By ALBERT P. BRUBAKER, A.M., M.D. 8vo, 752 pages. Cloth, illustrated, $3.00 net. P. Blakiston's Son & Co., Philadelphia.

HANDBOOK OF MEDICINE AND THERAPEUTICS. By ALEXANDER WHEELER, L.R.C.P. and S. E., and WILLIAM R. JACK, B.Sc., M.D., F.F.P.S.G. 12mo, 512 pages. Cloth, $2.50 net. William Wood & Company, New York.

PHYSICAL SIGNS OF DISEASES OF THE THORAX AND ABDOMEN. By JAMES E. H. SAWYER, M.A., M.D. Oxon., M.R.C.P. London. 12mo, 188 pages. Illustrated, $2.00 net. William Wood & Company, New York.

AIDS TO OSTEOLOGY. By PHILIP TURNER, B.Sc., M.S. (Lond.), F.R.C.S. 16mo, 188 pages. Cloth, $1.25 net. William Wood & Company, New York.

THE TREATMENT OF GONORRHEA IN THE MALE. CHAS. LEEDHAM-GREEN, M.B., F.R.C.S. 8vo, 160 pages. Cloth, illustrated, $2.00 net. William Wood & Company, New York.

Medical Items.

Hereditary Syphilis of the Long Bones.—Fr. Le Moine and J. Pénard give the histories of twenty cases of syphilis of the long bones. From their observations they draw two conclusions: The extreme difficulty of curing them when they have existed for a considerable time and the frequency of the occurrence of sequestra. The treatment of these lesions is to be entirely medical when observed early in the course of the disease. Energetic specific treatment will cause the quickest disappearance of the trouble and the least possible amount of deformity is left behind. When treated surgically we get decay of the bone, sequestra, and wounds that will not heal without loss of bone tissue. Such treatment is desirable only in late cases, which have been neglected and not given specific treatment. In very painful conditions which have resisted specific treatment surgical treatment is indicated. Specific treatment will not remove or cause to be absorbed hard bony formations. Multiplicity of lesions favors the diagnosis of syphilis. The study of the glands and viscera is of value, as is that of the family history. The *x*-rays are of value in disclosing the shape of the bony lesions.—*Gazette des Hôpitaux.*

Impacted Cerumen.—Much suffering from earache, as well as deafness (particularly in the aged) comes from impaction of cerumen in the external auditory canal. This may be readily removed by warming a little dioxide of hydrogen, pouring it into the ear while the patient is lying on a bed or table, and allowing it to remain for about five minutes. Then if the ear be gently syringed with warm solution of bicarbonate of sodium the plug will be easily removed. If not, it will be next day on repetition of the procedure.—*American Journal of Clinical Medicine.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending August 28, 1908:

THE RELATION OF THE MEDICAL PROFESSION TO THE HOUSING PROBLEM.*

By S. A. KNOPF, M.D.,

NEW YORK.

PROFESSOR OF PHTHISIOTHERAPY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; DIRECTOR IN THE NATIONAL ASSOCIATION FOR THE STUDY AND PREVENTION OF TUBERCULOSIS; ASSOCIATE DIRECTOR OF THE CLINIC FOR PULMONARY DISEASES OF THE HEALTH DEPARTMENT; VISITING PHYSICIAN TO THE RIVERSIDE SANATORIUM FOR CONSUMPTIVES OF THE CITY OF NEW YORK, ETC.

THIS distinguished body, the Academy, has honored me on repeated occasions by assigning important subjects concerning Medical Sociology and Hygiene to me for discussion, but never before have I felt such a weight of responsibility nor realized so much my temerity as in attempting to treat so vast a subject as the one I am to discuss to-day.

METHODS OF HOUSING.

All civilized men spend one-third of their lives indoors for sleep, and of all workers in the various fields of human activity by far the greater number have indoor occupations. According to the United States census of 1900, there were 29,073,233 persons over ten years of age engaged in earning their livelihood in some one of 303 specified occupations, out of which only 46 could be distinctly called outdoor occupations. The total number engaged in these latter were 12,058,671. The number engaged in the 257 indoor occupations would thus be 17,014,562. If we add to this the time all classes of people spend indoors for amusement, instruction, or worship, well may we say that the greater part of the people of the United States virtually spend their lives indoors. This statement alone is enough to show the importance of our subject.

In a most interesting pamphlet on the history and development of the Housing Movement in the City of Washington, my friend, Dr. George M. Kober, of that city says: "The primary object of habitations is to secure protection from the influence of heat, cold, rain, sunshine, and storms, and thus promote the health and happiness and indirectly also, the morals and culture of the human race."

In order to attain all these benefits, habitations must be built and equipped so that they offer warmth in winter, coolness in summer, and fresh, pure air and light all the time. Incidentally, I would say, it is furthermore necessary that these houses have such interior arrangements and utensils as will reduce to a minimum the danger of the appearance of endemics or epidemic diseases.

When we consider that tuberculosis, pneumonia, grippe, and bronchitis are perhaps the four diseases which are propagated through our present methods of housing the people, and when we furthermore consider that the first two diseases, tuberculosis and pneumonia, furnish at this time of our civilization the greatest morbidity and mortality, it would seem most wise and timely for the Academy to take up this serious question of the housing problem.

To do justice to our theme even in only a very small way it is necessary to limit the discussion to the housing of the well and the chronically ill. The housing or rather the hospitalization of the acutely diseased or surgically ill, the hygiene in day schools, kindergartens, factories, workshops, churches, and places of amusement, boats, ships and railroad cars, is too vast a subject to be dealt with at the same time.

All human habitations should as far as practicable be built on good porous soil, preferably coarse sand or gravel. Next best is rock, and only third in order comes clay.

I will now take up the various classes of houses; first, the private houses of the well-to-do, occupied by one or two families. Whether in the city or country they should, whenever possible, be built so that there will be no dark rooms. All the living rooms should have southern exposures; even at the risk of having the kitchen and the rarely frequented parlor facing north.

In large towns or cities in the absence of nearby playgrounds, house owners should, either by single endeavor or by combining with their immediate neighbors, provide a private playground for the children. If this is not feasible, the roof of the house should be transformed, with the aid of strong wire netting, into a safe roofgarden and serve as a playground for the children. In building individual private homes the sanitation often suffers from the desire for too many rooms. There must be a certain number, no matter how small, and usually they are badly lighted and ventilated for that reason.

I consider our American windows of which only one-half can be opened inferior to the French casement windows which allow twice the amount of bad air to escape and good air to come in.

In the construction of the better class hotels and apartment houses, in which so many American families now make their homes, the same criticism of small rooms, absence of playground for children, etc., holds good. In building hotels and apartment houses, I consider it well nigh criminal to raise them to such a height that the neighbors opposite or on the side are deprived of sunshine and light the greater part of the day. It would seem that a law limiting the height of buildings, particularly in the residential section of our American cities, is an urgent necessity.

*The above address was delivered extemporaneously with the help of a few notes before the American Academy of Medicine at its last year's meeting for the purpose of opening the discussion for a symposium on the subject.

The importance of the relation of the medical profession to the housing problem induced me to study the question still more thoroughly and to revise and rewrite the article carefully for publication in the MEDICAL RECORD. This accounts for the fact that the address is printed over a year later than it was delivered.

The problem of housing our laboring population in large cities, where owing to lack of transit facilities the masses must remain near their place of work, has baffled the minds of our philanthropists, city authorities, and sanitarians. The congestion in some of the large cities is something fearful to contemplate, especially in our city of New York. In some sections of the city more people live in a square mile than either in London, Paris, or Berlin.

Our only salvation from this fearful situation, not only for New York but for many other American cities, lies in extensive and good rapid-transit facilities concomitant with the building of sanitary homes in the suburbs for the laboring masses where they can have comfort and home life at reasonable rentals, and on the other hand the building of model tenements in the cities.

There is a third way of solving this problem which is known as the Garden City movement. It originated in England, and has already found its imitators in the United States in what is known as the Garden Cities Association of America. Permit me briefly to state the aim of this splendid humanitarian movement. Its object is the founding and development in the country of industrial garden cities, in which, amid beautiful and healthful surroundings, factories, stores, or other forms of business may be established, and where the workers may have attractive, though inexpensive homes, each with its own garden, and all to combine as many as possible of the attractions both of city and of country. The movement is patterned somewhat after the successful Garden City Association of Great Britain, which is now building its first garden city, at Letchworth, Hertfordshire, England.

An interesting item which I copy from an announcement by the American Association is the following: "It is known that many factories and employers, unable to increase and expand their business in the cities in proper ways and without enormous expense, are willing and anxious to move into the country if they can secure the right work people there. The Garden Cities Association therefore has undertaken one of the most important, far-reaching, and hopeful movements of the present day, and yet one for which the times are ripe, and which can be carried on in a practical business-like way. The Association believe that the one best thing which can be given workingmen is steady, well-paid work, with a good home in a garden city." Practical men, men of large means and broad ideas, have originated this association. Glancing over the names of the Board of Managers we come across such men as John Lewis Childs, President, W. D. Bliss, Secretary, Edward M. Shepard, August Belmont, Rt. Rev. H. C. Potter, Rev. Joseph Silverman, Prof. Felix Adler, Josiah Strong, and others of equal prominence in the world of philanthropy, commerce and science.

Our progressive Governor, the Hon. Charles E. Hughes, had, no doubt, such or a similar solution in mind when at the recent Congestion Exhibit in our city he said that the distribution of the people in more tenements on the island would not in itself suffice, but that there must also be a large distribution of centers of work.

Let us return now for a moment to a subject which for the time being at least is nearer and more urgent than this beautiful plan of garden cities. I refer to our tenement house problem. In New York City, thanks to our excellent tenement law and a tenement house department, created January 1, 1902, both of which in spite of unscrupulous politicians, greedy landlords, and heartless real estate speculators, are still in existence, conditions are much improved as compared with former times. While much has been done there is more to do. To give you an idea of how much there is still to be done, let me quote from an interesting article by Mr. L. H. Pink, which recently appeared under the title, "Old Tenements and the New Law," in University Settlement Studies, Vol. III. No. 2. The tenement house department in the five years of its existence has proved itself invaluable. It is well organized, at its head are clean and able officials: "Yet of the 362,000 dark rooms which were in existence when it was organized, but 6,000 have been provided with windows. Paul Cravath, Chairman of the Tenement House Committee of the Charity Organization Society, estimated that 'three generations will sleep in the smother of these unventilated boxes.' At the present rate it will take 86 years before light is let into the remaining 356,000 dark rooms. We cannot wait for 86 years for their removal."

In a more recent communication, dated May 2, 1908, Mr. Robert W. de Forest, president of the C. O. S., and former Tenement House Commissioner,

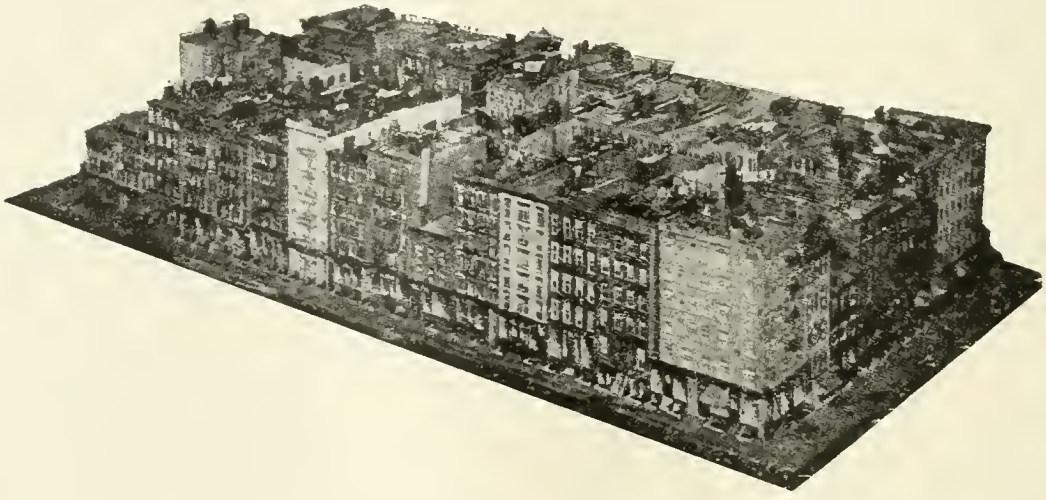

Fig. 1.—Model of an actual block on the east side of New York city as it stood January 1, 1900, block bounded by Christie, Forsythe, Canal and Bayard streets. The tenement houses in this block contain 567 different apartments for 2,761 persons. Of the latter 2,315 are over five years of age, and 446 under five years. The block contains 262 two-room apartments, 179 three-room apartments, 105 four-room apartments, and 21 five-room apartments, making a total of 1,586 rooms. There are only 264 water closets in the block. There is not one bath tub in the entire block. Only 40 apartments are supplied with hot water. There are 441 dark rooms, having no ventilation to the outer air, and no light or air except that derived from other rooms; 635 rooms get their sole light and air from dark, narrow "air-shafts." The rentals amount to $113,964 a year. This block has not been selected as one of the worst in the city. There are worse ones.

writes as follows: "More than 300,000 persons sleep every night in dark, unventilated interior rooms in tenement houses of this city. These rooms have no windows even to adjoining rooms. This state of affairs is largely responsible for the fact that 10,000 persons die of tuberculosis in New York City each year. Several thousand privy sinks and privies in crowded city yards still undermine the health of the tenement house population."

Many of the old houses cannot be made fit for use by human beings. Complete destruction is the only remedy. The law on its face gives to the Board of Health and to the Tenement House Department the necessary powers to destroy unsanitary dwellings, but in the Dassori case the Court of Appeals held that it is not enough to prove that a dwelling is unfit for human habitation; it must be unfit for any purpose before it can be torn down. This decision offers a loophole for escape and emasculates the statute. As a result the Tenement House Department has abandoned its efforts to demolish the rookeries. A new and comprehensive law, giving to some responsible body power to wipe out the plague spots, is our greatest need.

In 1903 I was privileged with many others to appear before His Honor, Mayor Low, to plead for the destruction of that horrible example of our modern way of housing the people, known to us New Yorkers as the "Lung Block." It is the block bounded by Catherine, Market, Cherry, and Hamilton streets. It surpasses all other sections of the city by its fearful mortality from tuberculosis. At No. 144 Cherry street there were no less than eleven cases in a single year. I have only been able to procure the photograph of a model which is not quite as bad, but which will give those who have never seen a crowded tenement house block in New York a fairly good idea of what is meant by dangerous congestion (Fig. 1).

I am free to confess that in view of the present condition of our social fabric, I do not think the tenement house problem can be solved without the philanthropists, and let me add the capitalist who will be satisfied with a reasonable interest on his investments.

The model tenement house, as I understand, has given to its owners six per cent. on the capital invested. If these capitalists could content themselves with four per cent. and allow the two per cent. which they could have in addition, to be given to the reduction of rent they would be both capitalists and philanthropists. What we need is more men like Mr. Phipps, who gave to the City of New York one million dollars as a perpetual fund for the construction of model tenement houses, under the condition that the earnings should be reinvested for the building of other model homes for the laboring classes. The possible objection to this plan is that in the desire to create more model tenement houses very soon, the rental price will be placed too high for the average laboring man. But I may be mistaken in this idea and should not wish to have it interpreted as a criticism of that unique and splendid philanthropy created by Mr. Phipps.

Fig. 2.—First Prize Plan for Model Tenements, by R. Thomas Short, New York.

What does a model tenement house mean? Instead of describing to you my own conception permit me to show you here a plan of a model tenement house suitable for any large city, designed by Mr. R. Thomas Short, a New York architect, at the time of our tenement exhibition (Fig. 2). To this plan the prize was awarded in a competition of one hundred and seventy-five architects. As you see, this plan is designed for a tenement house on a lot 100 feet wide by 100 feet deep. A space of 10 feet in width and 100 feet in length is left at the rear of the building for light and air, as required by the New York building laws. The main feature of the plan is the large street court, which in its narrowest part is 12

feet wide and one-half of which is 24 feet wide. This court is 60 feet in total depth, and provides an abundance of light and air for all the rooms. Being open to the street, it permits free circulation of air at all times, and has the additional advantage of giving a number of rooms an outlook upon the street, thus creating a greater number of "front apartments," and materially increasing the rental values of the building. The plan provides accommodations for fourteen families on a floor, having a total of forty-four rooms, and an abundance of closets. The lack of closet space has been one of the serious inconveniences of tenement house life. Besides this, the plan possesses the further advantage of having a private hall for every set of rooms, thus insuring privacy to the tenants. Every family has its own watercloset entirely within its own control. There is no part of the building more than two rooms deep. This is the secret of the whole tenement house problem, because it means that there are no dark interior rooms. Besides these many advantages, there are four light staircases and stair-

Fig. 3. Model Tenement Houses Built by the City and Suburban Homes Company, on First Avenue between 64th and 65th Streets.

case halls provided for the tenants, thus securing greater safety in case of fire, and removing to a large extent much of the social friction that exists in the ordinary tenement house. A large open court also provides a natural playground for the children, and does away with the necessity of subjecting them to the influences of the street.

The City and Suburban Homes Company erected recently on Avenue A, Seventy-eighth and Seventy-ninth Streets, two model tenements which are particularly sanitary and strikingly simple and beautiful (Fig. 3). In the erection of these buildings there were some modifications of Short's first-prize plan.

Another interesting experiment to solve the housing problem has been made in some cities, particularly in Washington. It deserves mention here because, like the model tenement house investment, it is safe and profitable and also a most humanitarian work. The Washington Sanitary Improvement Co. has built model homes, not tenement houses in the ordinary sense of the word. I cannot possibly enter here into a detailed description of these buildings but will, with your permission, give you a synopsis of the work of this company and show you a few photographs of some of their houses.* This company has for its principal officers two physicians of whose record as sanitarians and scientists, we, as Americans, may well be proud. I refer to Surgeon General Sternberg and Dr. George M. Kober. That this great work which in its scope has been a particular blessing to the heretofore so miserably housed colored population in Washington should have for its prime movers two physicians, one of whom is a fellow of this Academy, should be particularly gratifying to us.

The following is a résumé of the company's chief merits. (1) It has established a high standard of sanitary homes for wageearners at reasonable rentals; (2) It has erected two-story houses, each constituting a distinct and complete flat with separate entrances, exits, separate yards and cellars; (3) It grants one month's rent free to every tenant or so much thereof as has not been expended during any one year for interior repairs. Exterior repairs necessitated by the elements are not charged against tenants; (4) The company carries a full insurance against loss by fire and all repairs are made on the principle that "a stitch in time saves nine"; (5) By exercise of strict economy and careful business methods the directors have been able not only to pay 5 per cent. dividends on all money invested in the company from the beginning, but have also promoted the philanthropic aspect of the enterprise by providing the very best accommodations from the standpoint of hygiene, and as to comfort, the utmost which a given cost will permit.

While model tenement houses, small individual houses for the laboring population and garden cities are being created by philanthropists, public spirited citizens and capitalists satisfied with a mod-

*Limitations of space have necessitated the omission here of those interesting and instructive illustrations.

est interest, for the protection of those who cannot enjoy the privileges of any of these three enterprises we must have good tenement house laws and a rigorous enforcement of them. It is beyond the scope of this paper to suggest improvements in any existing tenement house law. You have already heard how our New York law considered formerly so good was proved defective. All tenement house laws of necessity must vary according to the geographical and topographical situation and particularly the size of a city or town.

What should be common to all of such laws is to require all light rooms, good ventilation for all rooms, perfect plumbing, proper heating facilities, and reasonable security against fire.

The problem of providing cheap but good individual homes for our laboring classes where land is cheap, but in a region easily accessible to their center of work, is a very important matter. To see how reasonably such a house could be built, I consulted with Mr. John Van Pelt, a practical architect of this city, who was good enough to make plans for me of a modest but convenient house, of which I give the following illustrations (Figs. 4, 5, and 6) and description:

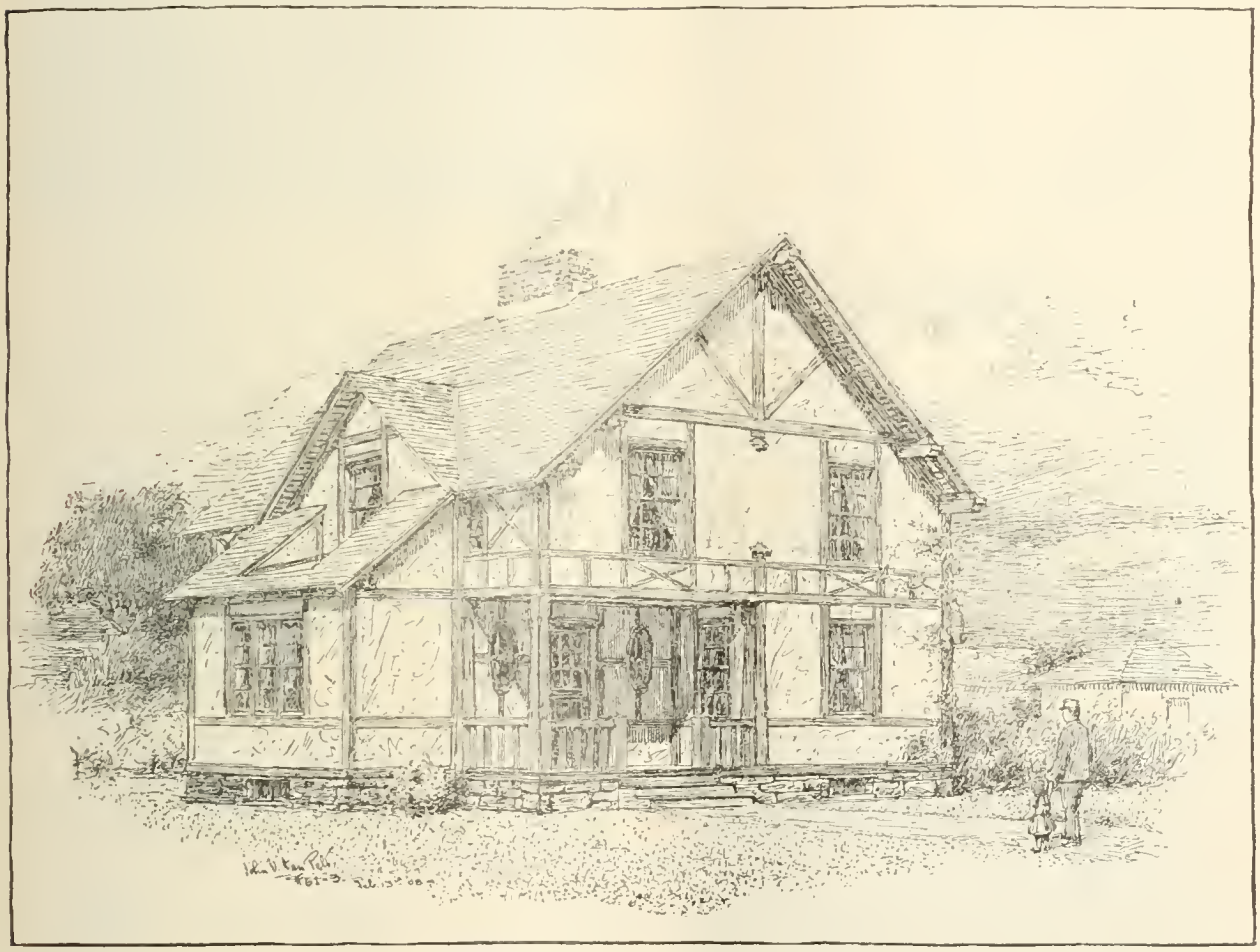

Fig. 4.—Workingman's economical house for one family.

"The building has been planned in the most economical manner possible. A single chimney, placed in the middle of the house affords a fireplace and contains flues from the heater and kitchen range.

"All rooms, except the smallest bedroom, have two windows in different walls, insuring cross ventilation. The fireplace in the living room acts as an aspirator for foul air and has a 12-inch x 12-inch flue. Hot air heating is adopted, with the cold air intake bringing air directly from the exterior, each room being provided with a riser, conducting this warmed air to the different parts of the house. The cellar stairs go down under the main stairs, and a door leading from these stairs to the exterior makes it possible to carry the ashes which descend to the ash pit in the cellar through a dust chute from the fireplace, and which also accumulate from the hot air furnace, directly out-of-doors without spreading dust through the house.

"The plumbing is centralized, a single soil pipe being sufficient, and the hot-water boiler is placed in a compartment behind the chimney so as to alleviate the conditions that lead to an overheated kitchen. The laundry tubs have been placed in the kitchen, as the wives of workmen must do all their work, and should be as near their family as possible. Space has been provided on the back porch for the refrigerator, a lattice surrounding the same to give shade.

"All of the bedrooms have closets and a broom and linen closet is also provided on the upper floor.

"In the interior treatment of the house dust-gathering projections are avoided as much as possible. Reentrant corners are rounded and a cove and sanitary base are used. The frame work is stud partition, with rubble or cement block foundation wall, according to locality. A half-timber effect is obtained with stucco in between, the house being sheathed and covered with building paper before the latter is put on. The roof is shingled.

"The house is piped for gas, but not wired for electricity on account of the expense. If the cost permits, such houses should be painted on the interior, the last coat being laid on flat; but if this is impossible, water color can be substituted.

"Under favorable circumstances, such a house should be built for $2,800. In smaller proportions it can be built for $1,650."

When, some time ago, I read in our daily papers of the promising invention of our great Mr. Thomas A. Edison. I decided not to publish this paper until

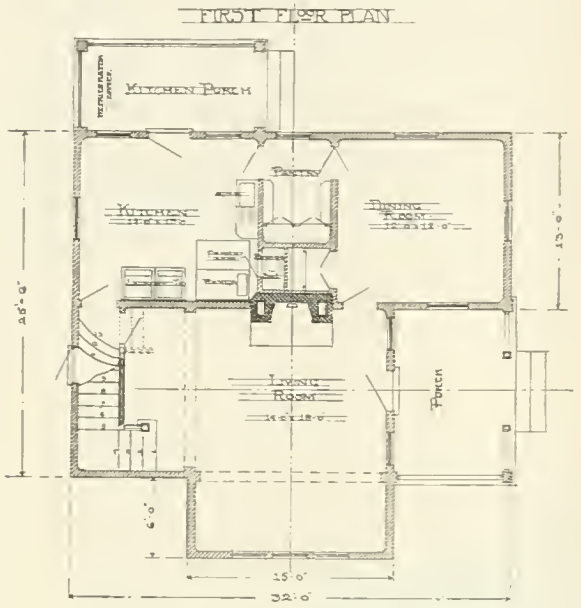

FIG. 5.—First floor plan of the workingman's economical house.

I had visited him and learned all about this new concrete house which would solve the problem of housing the laboring people in suburban districts and encourage home owning and home life to an extent of which we had never dreamt before. To have such a house monolithic, fireproof, durable, and arranged with all the necessary conveniences to make home life pleasant for the laboring man seems almost ideal.

I was granted a most cordial interview by Mr. Edison, who described to me in detail the construction of the house. The fact that it can be made in a simple style for one thousand dollars should certainly be an inducement to home seekers. That it should be eminently sanitary, and at the same time beautiful, will be seen from Mr. Edison's description:

"The reproduction shown here (Fig. 7) is made from the photograph of a model of the house for which Mr. Edison is constructing cast-iron moulds. These moulds are so made that portions can be taken off and other portions added, varying the completed design of the house in a number of ways. The moulds of the house are set up in their entirety, so that everything which may be constructed of concrete (stair railing, bath tubs, etc.) can be moulded in place. The inside and outside of the moulds are held in position by bolts covered with sleeves, the sleeve being left in the concrete after the moulds have been taken off. Holes are left in the floors so that heating and plumbing pipes and conduits for electric wires can be run through.

"The roof, which in this first design is modeled to resemble tile, will be painted or stained, and the walls will also be stained, the whole being waterproofed on the exterior. The windows are casement windows, and will be hung directly from the concrete openings. The sash of these windows and the doors will be the only wood on the building.

"While Mr. Edison's intention has not been to construct the more expensive class of house, and his idea is to build one which can rent profitably for $7 a month, he has intended to make the building as attractive as possible and perfectly hygienic and fireproof.

"The concrete is reinforced by reinforcing rods, which will be placed in the center of the moulds, and the buildings will therefore be practically indestructible. They can be washed out with a hose, and, owing to their construction, will be free from vermin. They are intended for sections of the country where the sand taken out of the cellar, with cement added to it, will be the only requisite for the construction. The walls of the house, 10, 8, and 6 inches thick, will be sufficient, with their exterior waterproofing, to preclude any danger from the penetration of moisture.

"Of course, the first of these houses has not yet been actually constructed, but Mr. Edison's proposition appears perfectly feasible, and if the houses are built in large enough numbers, it seems almost certain that their cost will not be more than he anticipates. Mr. Edison's intention is that, in the future, companies will be formed, having moulds made from the plans of their own architects, and constructing houses from these moulds as they may see fit, his only restriction being that the designs of the houses and material used shall meet with his approval."

The next subject which we have to consider is the problem of lodging houses. Those of you who have ever visited a cheap private lodging house, will understand why I favor municipal lodging houses which are of necessity under better control. My visits to lodging houses in the various parts of the country have shown me that owing to the large number of individuals who usually occupy these hostelries, the ventilation is always insufficient, particularly at night. If there are any class of buildings where our American windows should be replaced by the French type, which permits twice the

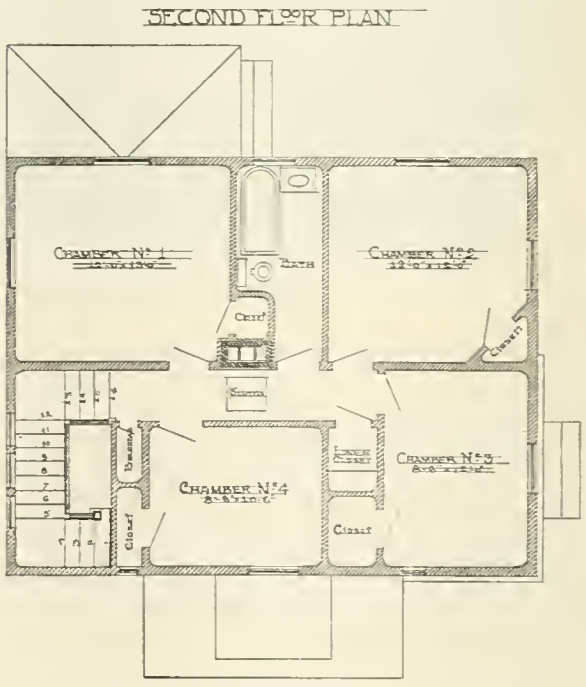

FIG. 6.—Second floor plan of the workingman's economical house.

amount of fresh air to enter and foul air to escape, it is in our private and public lodging houses.

While I intend in the second portion of my address to treat the interior arrangement of our average dwellings, I believe it may be well at this point to call attention to section 26 of our law relating to lodging houses. It provides that the beds in all

lodging houses shall be separated by a passageway of not less than 2 feet horizontally, and all the beds shall be so arranged that under each of them the air shall freely circulate, and there shall be adequate ventilation. Four hundred cubic feet of air space shall be provided for each bed and lodger, and no

Fig. 7.—Model of Edison's monolithic concrete house.

more beds shall be permitted than those provided in this way, unless free and adequate means of ventilation exists, approved by the Board of Health, etc.

If we could apply the best tenement law and lodging house law to some of our boarding schools, our asylums for the old and infirm, our orphan asylums, prisons and reformatories, there would be less morbidity and less mortality from infectious and communicable diseases in these institutions.

I do not desire to be misunderstood when I classify our prisons and reformatories as institutions which, regarding constructions and sanitary arrangement, should be placed on the same level as boarding schools and asylums for orphans, the old, and the infirm.

A prison by its very nature cannot and perhaps should not be made too comfortable a home for the morally diseased. However, when we build prisons we should select good soil to build upon, and not one like, for example, the Sing Sing Prison soil. When upon the invitation of the Prison Association, I visited that institution, I found what would have been an excellent and sanitary prison had it not been for this deficiency. The soil on which the Sing Sing Prison is built is constantly moist, and the stone walls retain the moisture to an alarming degree, so that the lower tier of the cell building is certainly thoroughly unfit for any human being to live in. The upper tiers are somewhat better, but they too are moist enough to foster tuberculosis as well as the damp soil will do.

Such disease-producing conditions can and should be avoided in selecting proper ground upon which to build penal institutions. Cells should never be smaller than 500 to 600 cubic feet, well ventilated, well lighted by natural light in daytime and by electric light at night (gas illumination absorbs too much oxygen).

All sanitary conditions tending to improve the physical and moral condition of the prison inmates should be thought of in the building arrangement and internal equipment of cell houses as well as workshops. It is our right and duty for the good of society to confine the criminal and punish him according to the gravity of his offense, by years of seclusion. But, however great the crime he has committed may be, we have no right to sentence him to contract tuberculosis or any other disease. Even leaving aside all altruistic considerations, for reasons of protection and self-preservation it is our imperative duty to do everything in our power to isolate all tuberculous prisoners, to treat every prison inmate afflicted with tuberculosis, and to give each one the best possible chance of cure. By adhering to this policy there will be fewer tuberculous prisoners discharged upon the community, and consequently a diminution of centers of infection.

INTERNAL ARRANGEMENT AND SANITATION.

What is the common defect in all our homes, rich and poor alike, hotels and lodging houses, asylums, and public homes for young and old?

We select for our bedrooms, as a rule, not the best but the worst lighted apartments. The majority of our city apartment and tenement houses are built in such a manner that only the two end rooms of the flat receive direct air and light. Thousands and thousands of persons in our large cities are thus compelled to spend their nights in rooms where sunlight has never entered. The strange custom of reserving the very best room, that is to say, the best lighted and best ventilated, to receive an occasional guest is not confined to country folks and poor city apartment or tenement dwellers. I have seen this done by well-to-do people who could have done better and should have known better. I recall here one instance from my own practice where two anemic children of six and eight years of age were forced to sleep in a dark bedroom, play in the dark dining-room and smelling kitchen, while the large front room, the so-called parlor with two large windows where the sun was streaming in a good part of the day, was locked all the week except on Sunday when visitors were expected. The little ones were not allowed to come in for fear that they might do harm to the good furniture. It was with the great-

Fig. 8.—Humidifier.

est of difficulty that these otherwise good parents were persuaded to transform the large parlor into the bedroom and playroom for the children.

The fear of night air, this nightmare of our ancestors, has not a little to do with the development and propagation of indoor diseases. In this respect I believe our institutions, or let me rather say, the heads of institutions which have dormitories for their inmates are the greatest violators of the first principle of hygiene. To have two or three, and sometimes four, children sleep in one bed, whether

in a private home or an institution, should be considered as absolutely unhygienic. The family practitioner should strive wherever he can to make people use the best lighted and best ventilated rooms for bedrooms and sitting rooms, and insist wherever he can on single beds for each member of the family.

In order to get an authoritative opinion on the best method of heating, which I may suggest in this paper, I consulted again with my friend, Mr. John Van Pelt, who is an expert architect and a former professor of the School of Architecture at Cornell, and who has been so helpful to me in my sanatorium plans. The following are his views on this important subject:

"The best method of heating buildings, in general, is one that brings warm fresh air into the rooms. The objection to a furnace is that it overheats a small quantity of air which it forces into the rooms after it may have been burned. Therefore, a better system is a direct system of heating, whereby a large quantity of moderately warmed air is brought into the room, say over steam, or better yet, hot water coils. A hot air furnace installation is the cheapest, and is, therefore, the best that can be used for the poor. Ordinarily, the poor heat with stoves which combine the objectionable features of systems that heat the air contained in the

Fig. 9.—Direct reading hair-hygrometer.

rooms without changing it with the objections of systems that burn the air; moreover presenting great danger of allowing gas to escape. Especially is carbon monoxide given off through the pores of the iron when these stoves become red-hot. The usual systems adopted in homes on account of the balancing between expense, convenience, and hygienic reasons are steam heat, or better, but more expensive, hot water with radiators placed directly in the rooms. There are so many cracks in the ordinary house that considerable ventilation is assured. Moreover, most houses have fireplaces which promote some ventilation even if there is no fire burning. As you know, most of our American houses are too tightly built, are kept at top high temperature, and the air is not changed often enough."

Might I add here that we are not only accustomed to keep our houses at a top high temperature, but that we have the air altogether too dry. I have taught and preached against this practice so dangerous to our health, quite often and considered the subject important enough to incorporate a little discussion of it in my prize essay, "Tuberculosis as a Disease of the Masses and How to Combat It." Experience has proven that we can be perfectly comfortable in a temperature of 65° F., and even a little lower, provided the relative percentage of moisture is 60. If this moisture falls to 30 or 20 per cent., then the dry throat, dry nose, and dry skin are in evidence. The explanation is simple. The dry air absorbs the moisture from the body and causes discomfort. The drying of mucous membranes in this way lays them open to the invasion of the organisms, causing colds, grippe, pneumonia, and tuberculosis.

The excessively dry atmosphere of many city and country homes in winter often gives rise to nasal catarrh, a condition which everybody, but especially those suffering from pulmonary diseases or prone to them, should be anxious to avoid. Besides keeping the water pan in the furnace constantly filled, there should be in the sitting room and sleeping rooms some humidifying arrangement, such as the one known as the humidifier (Fig. 8). More simple evaporating devices, however, such as a vessel filled with water and a cloth suspended above it touching the water, so as to produce capillary attraction, will answer the purpose of rendering the atmosphere sufficiently humid. To determine the proper humidity the direct reading hair hygrometer answers all practical purposes (Fig. 9).

After vitiated air, dust is the next most important factor as a disease-producing and a disease-propagating agent. Even the so-called sterile dust of the mineral or vegetable kind, if constantly inhaled, will irritate and inflame the respiratory tract and leave the mucous membrane in a condition for a ready invasion by any of the pathogenic microorganisms. It must be remembered that even in the normal individual we not infrequently find the pneumonia-producing pneumococcus and the Klebs-Loeffler bacillus which is the specific organism of diphtheria. The individual a little below par in general health or who has his upper respiratory tract irritated by the constant inhalation of dust, may thus fall a prey to the microorganisms of pneumonia or diphtheria of which he was the host, or to the bacillus of tuberculosis or of grippe from external sources.

The dust problem is so great and so important that we should give it our special attention. The greatest amount of dust and dangerous dust in houses is that kind which is carried in on the soles of our shoes and may I say, with apology to the ladies, by the aid of long, trailing skirts. It is to be hoped that the requirements of health will continue to dictate to fashion, and that trains will never again be seen on our streets. In the opposite event I am willing to be put down as one who favors the enactment and the enforcement of a law prohibiting the trailing of skirts in public highways.

The streets should, of course, be sprinkled regularly in dry warm weather. While flushing them with a moderate force of water is excellent, too great a force wears pot holes in the asphalt paving, thus doing more harm than good. A sprinkling cart or a hose of small caliber should be used. If the street car companies could be induced to cooperate with the city by sprinkling their tracks, much comfort would surely be assured to their patrons and some of the dangers from dust removed.

Any one who has noticed the cloud of dust that follows a swiftly moving car or the amount that is carried in by the back draught when the weather permits having the rear doors open, would appreciate the abatement of this unhygienic and unpleasant condition.

What can be done to diminish the quantity of dust which we are bound to bring into our homes on the soles of our shoes and on our garments? Let me suggest to you here a few devices, the utility of which I learned to appreciate in my studies in the prevention of carrying dust into sanatoria for the

tuberculous or into the homes of consumptives. There should be first a sort of grate and beneath it a receiving pan for the purpose of freeing the soles from the greatest amount of dirt attached to them. Next to this grate there should be a sort of apparatus composed of two blocks over which is stretched a slightly moistened canvas. After a thorough cleaning over the grate one passes his soles over this moistened canvas for a final cleaning.

There is no better way of diminishing the amount of street dust brought into our homes than to make it a practice when we wear overcoats or dusters to place them in a wardrobe situated near the door, and brush them as well as all other garments in the open air, and not as our Pullman car porters do in the midst of a close apartment crowded with people. Just as I consider sweeping a dry street a crime against one's fellowmen, so do I consider the just-mentioned practice a criminal nuisance. It is astonishing how much less dirt is carried into the rooms if these two simple devices are conscientiously used.

Against dust blowing into the rooms from the street traffic, building of houses and burning of soft coal, the individual is of course powerless. Appropriate city ordinances and their enforcement are the only remedies. However, we, as physicians, can do something by teaching the families for whose health we feel ourselves responsible, how to avoid the accumulation of dust in the homes by doing away with such articles of furniture which might well be termed dust catchers or accumulators. I refer here to all tapestry, instead of wall paper or a wall finish which can be washed; to all heavy cloth or velvet portières and curtains; to all fixed carpets, and last but not least to the innumerable articles of bric-à-brac not under glass cover, which adorn our American homes.

And now one word about the method of cleaning, that is to say, sweeping and dusting. There is no shadow of doubt in my mind that the ideal way, the most sanitary process of freeing our homes from accumulated dust is the modern method of vacuum cleaning, or exhaustive process. But before the average citizen will be able to allow himself this luxury or our tenement dwellers be privileged to avail themselves of the process, a goodly number of years will elapse. Yet we, as hygienists and physicians having the welfare of our families at heart, can do something in the meantime; first, by insisting that a feather duster should be forever banished from the hands of our women. It is surprising with what tenacity our house cleaners stick to this abominable instrument, which never cleans, but only displaces the dust from one section of the room to another. All the energy ever expended on cleaning with a feather duster has been not only useless, but one of the most powerful disseminators of the diseases of the respiratory organs. Like an instrument of ancient barbarism, the feather duster should be relegated to oblivion and be replaced by a slightly moistened cloth.

How may we diminish the dust in sweeping? Here may I suggest the method by which we try to teach the mothers in the homes of our consumptive poor? It is a leaflet composed by the distinguished Prof. T. Mitchell Prudden, of Columbia University and of our Tuberculosis Committee, and reads as follows:

"SWEEPING AND DUSTING.

"When you sweep a room, raise as little dust as possible, because this dust when breathed irritates the nose and throat and may set up catarrh. Some of the dust breathed in dusty air reaches the lungs, making parts of them black and hard and useless. If the dust in the air you breathe contains germs of consumption (tubercle bacilli) which have come from consumptives spitting on the floors, you run the risk of getting consumption yourself. If consumptives use proper spit-cups and are careful in coughing or sneezing to hold the hand or handkerchief over the nose and mouth so as not to scatter spittle about in the air, the risk of getting the disease by living in the same room is mostly removed.

"To prevent making a great dust in sweeping, use moist sawdust on bare floors. When the room is carpeted, moisten a newspaper and tear it into small scraps and scatter these over the carpet when you begin sweeping. As you sweep, brush the papers along with the broom and they will catch most of the dust and hold it fast, just as the sawdust does on the bare floors. Do not have either the paper or the sawdust dripping wet, only moist.

"In dusting a room, do not use a feather duster, because this does not remove the dust from the room, but only brushes it into the air so that you breathe it in; or it settles down and then you have to do the work over again. Use soft, dry cloths to dust with, and shake them frequently out of the window; or use slightly moistened cloths, and rinse them out in water when you have finished; in this way you get the dust out of the rooms. In cleaning rooms you should remember that dust settles upon the floors as well as on the furniture, and is stirred into the air which we breathe, by walking over them. You can easily remove all this dust in rooms which have bare floors, in houses, stores, shops, schoolrooms, etc., after the dust has settled, by passing over the floor a mop which has been wrung out so as to only be moist, but not dripping wet."

In recommending the foregoing rules, I have found housewives who object to the use of a moistened cloth to wipe the varnished woodwork and furniture. They claim that the appearance is spoiled thereby. To overcome this objection I recommend the use of a little crude oil and turpentine or some harmless furniture polish on the cloth which will make the dust cling to it as well as if it had been dampened with water.

When we consider the more recent studies in the etiology of many of the infectious and communicable diseases, we must bear in mind the common housefly and the mosquito. It has been well demonstrated that the housefly is a very frequent carrier of tubercle bacilli. When this insect has had an opportunity to feast upon tuberculous expectoration one can almost always find in its excrements the still virulent tubercle bacilli. It must be obvious that when such excrements are deposited on exposed articles of food, bacilli can enter the alimentary tract of either adult or child.

Tuberculous infection of the intestinal canal in children is so frequent that this probable source should be taken into consideration in our preventive measures. The housefly is, however, not only a danger during its short existence as a living insect, it becomes a source of infection even after death when during life it has had a chance to ingest tuberculosis germs. Virulent bacilli of tuberculosis have been found in the dust resulting from the crumbling of the bodies of dead flies. Thus there is a chance that the fly may even be the cause of the contraction of tuberculosis by inhalation. It would seem that we could with perfect safety assume that the housefly will carry all other infectious diseases in the same manner.

The brilliant work of the immortal Major Reed

and his coworkers has shown us that we must hold certain species of mosquitos responsible for yellow and malaria fevers (*Stegomyia fasciata* for yellow fever and the *Anopheles punctipennis, A. maculipennis* and *A. crucians* for malaria). While the total extermination of either fly or mosquito will be difficult, some preventive measures to diminish their number and danger in our homes can be carried out.

Wherever there are cuspidors or other receptacles to receive expectoration they should be covered when not in use. Even in institutions for the tuberculous where one often finds cuspidors outdoors, they should have a cover to prevent insects or animals from coming in contact with them.

Screens for windows and doors and ample protection by the aid of mosquito nettings during sleep in regions infested with mosquitos, fly paper, and the covering of all eatables are up to this date the simplest known precautions by which we may diminish the number of these insects and their danger as disease carriers.

We must also mention here, in connection with interior hygiene that dogs, parrots, and other house pets of the animal kingdom are at times carriers of infection. Tuberculosis, for example, has been contracted from parrots and dogs, and the echinococcus, when contracted in our country, can almost invariably be traced to the dog which has been a pet of the individual.

In conclusion, let me refer to a phase of philanthropical work carried on by the Association of Practical Housekeping Centers, which, to my mind, is destined to help in the housing problem of the people, perhaps as much as the building of the model tenements. This association has for its object to improve the sanitary and living condition of the tenement houses by the practical education of the tenement dwellers. A practical housekeeping center teaches, by precept and example, something of the art of living to all who come to visit these unique educational establishments, also known as model flats. I have visited one of these myself and watched with interest the enthusiasm of teachers and pupils. At the head of this work in New York are such well-known and practical women philanthropists as Mrs. Edward F. Dwight, Miss Mabel Hyde Kittredge, Mrs. Florence Kelley, Mrs. Hayden Richardson, Miss Lillian D. Wald.

The practical housekeeping centers try experimentally to meet the need of the mothers of to-day, of to-morrow, and of ten years hence. In a most admirable article, written by Miss Florence Kelley, for the *Century Magazine,* February, 1907, under the title of "Unskilled Mothers," reference to the subject is made in the following words: "If the practical housekeeping centers can be made permanent and numerous enough, if they can be made as much a part of the life of the community as the public schools are now, integrated in time with the schools, these problems, intemperance, infant mortality, and reduced vitality of the working class families, can be reduced to their lowest terms. Clean, orderly homes, in which air is pure, food is attractive and wholesome, and beds are clean and comfortable, give the baby the maximum chance for life and health, and his father an opportunity for keeping himself fit for his work, and a hope of escaping his deadliest enemies — drink and tuberculosis. These centers furnish a legitimate social outlet for activity among young people in congested centers, as well as in dull country towns. They promote health and right living among people of all ages."

REMARKS ON ACUTE INTESTINAL OBSTRUCTION WITH ESPECIAL REFERENCE TO INTUSSUSCEPTION.*

By EDWARD W. PETERSON, A.M., M.D.

NEW YORK.

ADJUNCT PROFESSOR OF SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Aside from acute gastric and intestinal perforations, there is no condition in the whole field of abdominal medicine and surgery, fraught with such real danger to the patient, and attended with such grave responsibility to the physician, as acute intestinal obstruction. If the fecal current is arrested suddenly from any cause there develops immediately a plight which is incompatible with life. The great abdominal nerve plexuses are thrown into a state of violent disorder; putrefactive changes in the intestinal fluids rapidly follow. If in addition to obstruction there exists strangulation of the blood supply to the gut—then we have an affection which, unless mechanically relieved, is rapidly and invariably followed by dissolution and death.

Etiology.—Anything which suddenly blocks the passage of the intestinal contents, must be considered as a cause of acute intestinal obstruction; for this reason the following classification is used:

- I. Congenital Obstruction
  1. Imperforate anus.
  2. Intestinal occlusion or stenosis.
  3. Volvulus due to torsion of the umbilical cord and to inflammation of the mesentery.
  4. Bands.
- II. Acquired Obstruction
  1. Intussusception.
  2. Strangulation...
     - *a.* Hernia, external or internal.
     - *b.* Omphalomesenteric remains.
     - *c.* Bands.
     - *d.* Adhesions.
  3. Volvulus.
  4. Obturation.....
     - *a.* Gallstones.
     - *b.* Enteroliths.
     - *c.* Tumors.
     - *d.* Foreign substances.
  5. Pressure obstruction, *e.g.* by displaced organs, tumors, etc.
  6. Intestinal paralysis.
  7. Infarction of the mesenteric vessels.

A detailed description of the different varieties above mentioned will not be attempted, for such can be found in any of the standard works on surgery.

Symptoms.—The cardinal symptoms of acute obstruction are pain, vomiting, and persistent constipation. The general picture is one of shock, accompanied by marked restlessness. The face is pinched and anxious and the eyes are sunken. There is more or less cyanosis, due to impeded respiration. Respiration is accelerated and shallow, and even the tone of the voice may be altered. The skin is clammy, the extremities cold, and the temperature is often subnormal. When the temperature is elevated, it is due either to the absorption of the toxins or to the presence of peritonitis. Thirst is extreme and the tongue is dry. Hiccough is often distressing. The pulse is small, weak, and rapid. The urine is scanty, high colored, or may be suppressed; usually it contains an excess of indican, indicanuria being especially marked when the seat of the obstruction is high. Abdominal tympany usually develops late and varies greatly, according to the nature and site of the obstruction. The lower the occlusion in the intestinal tract, the more pronounced is this symptom; when the trouble is high up, tympany is either slight or absent altogether.

The presence and constancy of the symptoms enumerated will depend, of course, upon the location of the occlusion and upon the degree of ob-

*Paper read before the Alabama State Medical Association, April 22, 1908.

struction and strangulation. It is well to analyze further the prominent symptoms.

Pain in some degree is uniformly present. It is due (1) to the mechanical injury to the bowel and mesentery by the constriction; (2) to the violent peristaltic efforts of the intestines to break past the obstructing barrier; (3) to gaseous over-distention of the bowel above the point of stricture. The character of the pain varies; it may be intermittent and colicky, or continuous and intense. It is usually severest at the point where the obstruction exists. This rule, however, is not invariable. In internal strangulation it comes on abruptly, is agonizing in character, and continues with but slight remissions. In volvulus, and especially in intussusception, the pain is at first paroxysmal, with intervals of comparative comfort, but later there is an increase in the frequency and intensity of the spasms. The sudden cessation of pain means either the relief of the occlusion, or the presence of gangrene or perforation. In the common varieties of obstruction (intussusception and volvulus being exceptions) abdominal tenderness is usually absent or slight during the first few hours. In fact, pressure will often give considerable relief to the discomfort. Later, tenderness is apt to develop.

Vomiting, as a rule, appears early; the higher the occlusion, the more frequent and distressing is this symptom. The vomitus consists first of the stomach contents, then of a greenish fluid containing bile, and finally of a dark fluid with fecal odor. The presence of actual feces in the vomitus is rare, and occurs only when the occlusion is low.

Constipation is a constant symptom; it is absolute and persistent in every type of acute obstruction, after evacuation of the intestinal contents below the point of constriction. Constant desire to go to stool, with the passage of mucus and blood, unmixed with feces and unaccompanied by flatus, is pathognomonic of intussusception.

Diagnosis.—As prompt radical treatment constitutes the essential element of success, it is of the most importance that an early diagnosis be made in acute obstruction. It would seem that the recognition of this condition would be comparatively easy, and it is so in most instances, but the following affections may cause confusion, *viz.*, phlegmon of the abdominal wall, inflammation of a retained testicle, fulminating appendicitis, acute pancreatitis, perforating gastric or intestinal ulcer, the twisting of the pedicle of a tumor or viscus, etc. In these affections there may be pseudo-obstruction reflexly caused by temporary intestinal paralysis. The remarks of Dr. Bar, before the Liverpool Medical Institution, very strikingly illustrate the necessity of discriminating between the true and false types. Dr. Bar said: "If you look upon all cases where you have got severe pain in the abdomen, constipation, and vomiting, with perhaps more or less shock, as cases of intestinal obstruction, then, no matter what line of palliative treatment you adopt, you ought to have a very good percentage of recoveries; but if you belong to a more exclusive school, and in your anxiety for accurate diagnosis, eliminate all cases of colic, constipation, enteralgia, etc., then you will find you have a terrible disease left, which tends more frequently toward a fatal issue than to recovery."

A carefully elicited history and painstaking physical examination will enable one to differentiate between the inflammatory diseases mentioned and mechanical obstruction. To take up in detail the points of differentiation is unnecessary and would consume too much time. In any doubtful case an examination of the blood, especially a differential leucocyte count, with regard to the percentage of polymorphonuclear cells, will be of material assistance. After a diagnosis has been made, one should try to ascertain the nature and site of the obstruction, as this knowledge will be of material help in carrying out the measures of relief. Generally speaking, the part affected in acute obstruction is the small intestine.

Internal strangulation is a cause in about forty per cent. of all cases. It is most common in young adults, comes on abruptly, with agonizing and continuous colicky pain and with early and distressing vomiting. Shock and collapse develop more quickly in this than in any other variety of obstruction.

Volvulus occurs almost exclusively in middle or advanced life and is much more frequent in men than women. The sigmoid is usually involved, and distinct tumefaction and tenderness can be felt with the palpating hand. Tympany develops early and increases rapidly. Vomiting is a late and unimportant symptom. Tenesmus may be present, but there is no discharge of blood from the rectum.

Intussusception is probably the most frequent cause of acute obstruction. While it may occur at any age, it is preeminently a disease of infancy and childhood. Fully seventy per cent. of all cases occur during the first year of life.

Treatment of acute obstruction.—No class of cases are more habitually mismanaged and conscientiously maltreated than the ones under consideration. Where palliative measures are depended upon, recovery is the exception, death is the rule.

Will distended gut ever burst a constructing band? Can a volvulus become untwisted? Does an internal strangulation ever undergo spontaneous reduction? Can an intussusception become disinvaginated, and recovery follow the sloughing and discharge of the intussusceptum? Yes, these things do happen occasionally, but if one awaits or expects such results, ninety to ninety-five per cent. of the cases so treated will die.

As a general rule, the distention of the colon by hydrostatic pressure, the insufflation of the bowel with gas, abdominal taxis, massage, etc., are not only unscientific and useless, but in some instances are positively dangerous. Puncture of the intestine through the abdominal wall for the relief of tympany is mentioned for condemnation only. Inversion and violent shaking of the patient are apt to do more harm than good. The administration of shot or metallic mercury, employed in olden times, is mentioned merely as a curiosity in the way of treatment.

Do not give purgatives, as they increase the pain and vomiting, and add to the risk of gangrene, perforation, and peritonitis. They can accomplish no possible good. Use opium very cautiously, for this drug so masks the symptoms and obscures the general picture, that it leads too often to fatal delay in the employment of radical treatment. Do not employ stomach lavage, except for diagnostic purposes or until a diagnosis has been settled, for this measure has almost the same sedative effect as opium, and is apt to give the attending physician a feeling of false security. After a diagnosis is determined, lavage of the stomach and colon should be carried out, for it lessens the vomiting, the pain, and the absorption of toxins, and also renders safer the administration of an anesthetic.

Generally speaking, a prompt laparotomy, quickly performed, is by all odds the safest, the simplest, and the surest method of accomplishing a cure. The operation itself, if performed early, is not more diffi-

cult or dangerous than laparotomy for the other intraabdominal lesions. A general anesthetic is contraindicated in cases seen late, where shock and collapse are pronounced, for in such a state, a narcotized patient is in danger of drowning in his own vomitus. Here the operation should be performed under local anesthesia, with, perhaps, the addition of morphine and hyoscine.

There is no single measure so useful in combating the shock of intestinal obstruction cases in general as the intravenous infusion of normal salt solution. It strengthens the heart, allays the extreme thirst, and stimulates the urinary flow. Of drugs, the most valuable is sparteine sulphate, administered hypodermically; it slows and strengthens the heart and has decided diuretic action.

After an obstruction has been relieved there are one or two practical points which will add greatly to the comfort of the patient. The stomach should be washed out immediately, and as often thereafter as indicated. Eserine salicylate should be started at once. This drug will aid in reestablishing normal peristalsis and by its action will lessen or prevent tympanites. Hot saline solution should be given by rectum, at frequent intervals, or, if necessary, it can be given continuously. The bowels should be moved by enema when they do not act spontaneously, rather than by drugs per mouth.

Each case of intestinal obstruction is a law unto itself, and must be managed in accordance with the principles of good surgery and with regard to the experience of the individual operator. The management of intussusception alone will be considered in detail. In this variety of obstruction, the diagnosis is easy and the indications for treatment are quite definite. Formerly, operation was considered only as a last resort; to-day laparotomy, with manual reduction, is the method of choice. Bouchut, in 1855, says, "The diagnosis of intussusception is uncertain and treatment powerless." Tanner (1871) after discussing taxis, etc., says, "Supposing these means fail, without absolutely recommending such a procedure, an exploratory incision into the abdomen would appear to be perfectly justifiable in an apparently hopeless case." Ashhurst (1881) says, "Past experience gives no encouragement to operative interference in cases of intussusception in infants less than one year old." Monyhan quotes Barker as saying that "He had never seen recovery after resection in gangrenous cases and never expected to see it." (These quotations have been borrowed from the interesting articles of Rushmore and Coffey.)

The writer, in a series of intestinal obstruction cases, has had five of intussusception in infants under one year of age. There were three recoveries and two deaths. In three of the cases gangrene had already set in, necessitating resection of the gangrenous intestine in two, and enterostomy in the third. The histories of these will be given later.

Unless acute intussusception is recognized early and treated promptly, the result is almost always fatal. Spontaneous reduction has been known to take place. Cases have recovered after sloughing of the intussusceptum, firm adhesions forming at the neck of the intussuscipiens. Such results are, however, never to be awaited or expected. If a case is seen early, say not later than six or eight hours after a diagnosis is possible, an attempt should be made by means of posture, gentle manipulations, and enemata to reduce the invagination. Such measures might succeed in "colonic" intussusception, are of doubtful value in the "ileocecal" variety, and are useless in the "enteric" type. The sooner we come to regard intussusception in the light that we look upon strangulated hernia and fulminating appendicitis, that is, as a condition demanding immediate operative interference, the more lives will we save.

Early laparotomy is the least dangerous and the most successful method of treatment.

There are points about the operation itself which deserve attention. The work should be performed quickly, or rather with "speedy deliberation." As three-fourths of all cases originate in the ileocecal region, the incision should be made through or to the outer margin of the right rectus muscle. In relieving the intussusception, it is best to commence at the apex of the intussusceptum, and carefully "back up" to the point where the invagination started. If traction is made on the proximal end of the invagination, the gut is apt to be torn at the neck of the intussuscipiens. If gangrene has occurred or if reduction is impossible, resection and intestinal anastomosis should be performed. Removal of the appendix is positively indicated in nearly all cases of "ileocecal" invagination, and it is a good point to make appendectomy a step of the operation. In closing the wound, one should reinforce the catgut sutures, with through-and-through tension sutures, as the abdominal wall is subjected to a considerable strain.

The postoperative treatment is of great importance. The immediate danger is death from shock, and free stimulation is indicated to overcome this condition. The next danger is from the secondary enteritis and toxemia, which are present to a greater or lesser degree in all cases of intussusception. If opium is systematically employed, the enteritis is aggravated, and the toxemia accentuated. It is better to give a mild laxative, and to follow it with astringent intestinal antiseptics and bowel irrigations. Under such management the condition will improve.

Case I.—Ida A., aged 4 months and 20 days, of German-American parentage, breast-fed, well nourished, and healthy. Had never previously been sick. September 28, 1904, was somewhat restless and fretful, and the following day suddenly became very ill. After one large fecal movement, she began to have frequent discharges of blood and mucus, without the passage of gas or feces, also paroxysms of colicky pains and tenesmus, and occasionally spells of vomiting. A physician, who was called in, diagnosed the case as "bloody dysentery." The mother, becoming alarmed at the increasing severity of the symptoms, brought the child to the hospital on the afternoon of September 30.

On admission the infant was very restless, constantly whining or crying out; facial expression anxious and uneasy; eyes "tired looking" and somewhat sunken; tongue dry; abdomen slightly distended, but no visible tumor present; thighs flexed on abdomen. The extremities were cool, the abdomen hot, somewhat rigid, and tender on pressure. An elongated tumor could be felt running across in the direction of the transverse colon, and then downward into the left iliac region. Rectal examination revealed a softened cylindrical tumor about two inches above the anus; the examining finger when withdrawn from the bowel was covered with bloody mucus. The temperature was 102° F., pulse 146, and respiration 40. A diagnosis was made of acute intussusception, of probably not less than thirty hours' duration, and preparation for immediate laparotomy was ordered. At this stage any other measure was deemed not only useless, but dangerous.

Operation.—A two and one-half inch incision was made through the right rectus muscle; a small

amount of serous fluid escaped when the peritoneum was opened. Examination of the tumor confirmed the diagnosis of intussusception. Beginning at the distal end, or at the apex of the intussusceptum, with great care the reduction was attempted. The gut was acutely congested and edematous, and the serous coat readily tore. Firm adhesions between the last inch of ileum and cecum, with beginning gangrene, rendered impossible the complete and successful reduction of the invagination. Removal of the gangrenous gut was decided upon. Four inches of the ileum, the cecum, and an inch of the ascending colon were resected, the mesentery having first been ligated. Then an end-to-end anastomosis, by means of a small Murphy button, was made. After attending to the gap in the mesentery, the abdominal incision was closed in layers with catgut, and reinforced by three sutures of silkworm gut, through all the layers except the peritoneum. Dressings and bandage were applied, and the patient was returned to bed in a profound state of shock. Respirations were exceedingly rapid and temperature high, immediately following the operation. The pulse, while very weak, did not show depression corresponding to respiration and temperature. Stimulants were freely used to combat the shock. Vomiting was frequent and annoying for the first fifteen hours, after which time it gradually abated. Only one dose of opium (5 minims of paregoric) was given, and that not until vomiting had ceased. The bowels moved spontaneously on the afternoon following the operation. A moderately severe secondary enteritis soon developed; this was treated with astringent intestinal antiseptics and bowel irrigations. On the fourth day the temperature went up, and the child seemed to be in great pain. In looking for a cause for this, the examination revealed the fact that the button had passed down to the anus and was there lodged. The removal of the button was followed by an immediate improvement in the symptoms. The abdominal wound was dressed on the fifth day, and the lower end of the incision was found to be infected. This infection promptly cleared up, and the wound was entirely healed by the fourteenth day. The patient was discharged cured on the fifteenth day after operation.

To review the history of this case: A healthy, well-nourished infant suddenly became very ill, with paroxysmal, colicky pains, tenesmus, bloody stools, vomiting, fever, and collapse. Examination of the abdomen by bimanual rectal touch showed a "sausage-shaped" tumor. It will be seen that this patient presented the classical symptoms and fulfilled in an ideal way the text-book requirements of acute intussusception. Operation confirmed the diagnosis. The ileum, appendix, and cecum were telescoped into the colon. On account of adhesions and gangrene the invagination could not be completely and successfully reduced, so a resection was made with an end-to-end anastomosis between the ileum and ascending colon. After operation, the severe shock, high temperature, and vomiting, enteritis, toxemia, etc., gradually disappeared, and recovery ultimately ensued. (An interesting feature of the case was the early passage of the Murphy button.)

Case II.—Elsie M., aged nine months. Referred by Dr. G. R. Pisek, June 2, 1905. For two days the child had been suffering with abdominal cramps and vomiting. There were frequent passages of blood and mucus, but no feces were expelled. An elongated tumor on the left side could be felt abdominally and by rectum. Upon operation a two and one-half-inch incision along the outer margin of the right rectus muscle was made and an intussusception of the ileocecal variety was readily produced. The appendix was amputated. A prompt recovery followed operation. The patient was discharged cured seven days later.

Case III.—Romeo M., aged four months, admitted to hospital July 5, 1906. Two days before admission the baby was suddenly taken ill with cramps and vomiting. Cathartics and enemata failed to relieve the symptoms. Discharges of mucus and blood appeared on the second day. A tumor on the left side could be felt abdominally and by rectum. Laparotomy about forty hours after onset of symptoms disclosed a gangrenous intussusception of the ileocecal variety, which could not be reduced; resection of the grangrenous gut; end-to-end anastomosis; death from shock three hours later.

Case IV.—Margaret H., aged five months, admitted to hospital July 10, 1906. Illness began one week before with cramps, vomiting, and diarrhea. At first there were eight or nine loose blood-tinged stools a day. Later the discharges consisted solely of mucus and blood. The baby did not care to nurse, and lost weight rapidly; the condition was critical. Upon examination, a tumor could be palpated in the left iliac region, also by rectal examination. Laparotomy under ether anesthesia revealed a double invagination in the ileocecal region; the cecum and ascending colon were gangrenous; the cecum ruptured during attempts at reduction; the gangrenous gut was then brought out of the abdominal wound and held up with a glass rod. Resection was out of the question in this instance, as the patient was almost dead at the time of admission to hospital. Death occurred on the following day.

Case V.—Baby Baker, aged five months, of Jewish parentage, was admitted to the Babies' Wards September 16, 1907. The infant was breast-fed and well nourished, and had never been ill previously. Two days before admission to the hospital he became very restless and fretful, and seemed to be suffering from abdominal cramps. Vomiting commenced early and continued at frequent intervals. The bowels, previously regular, did not act naturally, nor did enemata give relief. On the third day blood and mucus were expelled, unaccompanied by feces and flatus. Upon examination, the abdomen was found to be moderately distended and very rigid. On the left side an elongated tumor could be felt abdominally and by rectum. The examining finger, when withdrawn from the rectum, was covered with bloody mucus. A diagnosis of "acute intussusception" was made and preparation for operation ordered.

Operation.—A three-inch incision was made through the right rectus muscle. As soon as the peritoneum was opened the small intestines, much distended, crowded out. The diagnosis of intussusception was confirmed, the invagination being of the "ileocecal" variety. Beginning at the distal end, or at the apex of the intussusceptum, with great care the reduction was attempted. Owing to the edematous and friable condition of the gut, adhesions having formed at the neck of the intussuscipiens, it was very difficult to reduce the last two inches of the invagination. This was accomplished, however, with very little damage to the serous coat of the bowel. The abdomen was closed in layers with catgut and reinforced with three silkworm gut sutures through all the layers except the peritoneum. Following operation, the temperature rose to 107.8° F., then gradually subsided, reaching normal about the fifth day. Vomiting was persistent and annoying for the first few hours, after which time it

gradually stopped. The bowels acted naturally on the second day. The secondary enteritis, which is always present in intussusception cases, was not severe, and yielded readily to appropriate treatment. The patient was discharged cured on the seventh day.

In the foregoing remarks, no attempt has been made to treat the subject of intestinal obstruction in other than a superficial manner. An effort has been made, however, to emphasize certain practical points. With a better knowledge of the mechanics, and with a more thorough understanding of the pathology, of the affection under consideration, will come a realization of the futility, in most instances, of palliative measures. The keynote to success will bear reiteration—"Early diagnosis, prompt radical treatment."

ABNORMAL MOTILITY OF THE STOMACH A VALUABLE FACTOR IN THE DIAGNOSIS OF GASTRIC LESIONS.

By MILTON R. BARKER, M.S., M.D.

CHICAGO, ILL.

In this paper I shall deal only with those findings revealed by an examination of the stomach contents, due either directly or indirectly to an abnormal motility of the gastric walls, made long before the appearance of those familiar objective and subjective symptoms, which differentiate gastric lesions, but the advent of which is *prima facie* evidence that the time for rendering the best service in these cases has past. And should the dyspeptic symptoms be due to malignant invasion of the stomach, to wait to demonstrate the condition by its well-known symptomatology means, in a large majority of cases, the sacrifice of the patient's life.

Hence, if we are to render the best service in gastric lesions, especially in cancer, we must differentiate them early and by some other measures than that of their familiar symptomatology, comprehend easily, but usually so late that they convey more of despair than hope so far as successful treatment is concerned. Therefore, upon the presentation of a case complaining of that symptom-complex to which has been ascribed the name dyspepsia, which we know may be the expression of the early manifestations of many gastric lesions, we set about the task to discover with which of these we may have to deal.

Our knowledge is greatly enhanced regarding the early differentiation of these conditions by a proper interpretation and careful classification of the different elements constituting that portion of the gastric contents the presence of which in the stomach after a test meal is due to the abnormal motility of the gastric walls.

These findings may be positive or negative, each condition being, perhaps, equally important in building a differential diagnosis.

Should we find on examination of the stomach contents diminished hydrochloric acid, pepsin, and lab ferment, mucus being absent, we might suspect that malignant disease was active in the stomach; but from these findings alone we could not make even a probable diagnosis of cancer. However, should we find in addition a positive decrease in gastric motility shown by the abnormally long period of time required for the stomach to become emptied after a test meal, we would be justified in so strongly suspecting the influence of malignant disease, as to advise exploratory measures, provided the Oppler-Boas bacillus was not present; if it were present a positive diagnosis could be made without the aid of exploration. If the Oppler-Boas bacillus was not present (and we should not expect to find it in these early investigations); and if the gastric immotility was positive, and the stomach contents were free or nearly so, of mucus, we should question the wisdom of the postponement of exploratory measures, as the golden opportunity for rendering the best service might thus be lost, the Oppler-Boas bacillus frequently not appearing until the disease is so far advanced that operative measures are futile. In other words, we believe that, because of the fact that gastric immotility and dearth of mucus in the stomach contents are such universal conditions in gastric cancer, when these persistently prevail we should strongly suspect cancer, and institute exploratory diagnostic measures.

The abnormal findings that characterize gastric cancer are due to the profound vicious influence of this disease upon all the gastric tissues. Impairment of all gastric functions commences immediately upon the invasion of the stomach by cancer; as the disease develops all gastric functions diminish correspondingly, and when the disease is fully established all normal functions are destroyed, regardless of how limited a portion of the gastric wall is perceptibly involved. The above seems to be opposed by the fact that cancer has been demonstrated in stomachs in which the gastric glands were functioning. In other words, cancer has been found in stomachs in which there was also present hydrochloric acid, lab ferment, and pepsin. These, however, we believe belong to that class of cases in which gastric ulcer was the primary lesion, and which has become invaded by cancer, but which is not yet totally malignant, hence a lingering in the stomach of a constantly decreasing quantity of its normal secretions. In these cases our most valuable diagnostic aid is the progressive loss of the normal intrinsic motility of the stomach walls, characterized by constantly lengthening periods of stagnation of food in the stomach.

It is true that the cancer-invaded stomach is emptied of its contents, but it is emptied in a desultory way, and by extrinsic forces rather than by normal intrinsic motility. The cancer-stricken stomach is a functionally dead organ and the gross contents, together with the chemical and microscopical findings, are usually characteristic of such condition. Among the first of these functions to be sacrificed, and that which prevails most constantly and therefore is most characteristic of the disease, is the loss of the normal, intrinsic motility of the stomach walls, characterized as above stated by an increasing stagnation of the stomach contents after test meals. When the above condition increasingly prevails an exploratory laparotomy will in most cases confirm the suspicion that cancer has invaded the stomach. And at this time much hope may be entertained for the successful removal of the disease by surgical measures.

To make a differential diagnosis of chronic gastritis from the stomach contents is not always easy. Malignant disease of the stomach and chronic gastritis resemble each other in that all of the normal constituents of the gastric contents in fully developed cases are absent in both conditions, excepting mucus, and this constituent is abundant in chronic gastritis, but absent, or nearly so, in cancer. The destructive influence of gastric cancer is as marked upon the mucous glands of the stomach as upon all other gastric tissue, and in well-developed cases

the mucous glands of the stomach are functionless.

Chronic gastritis destroys all gastric functions except that of the mucous glands. The most characteristic finding in the gastric contents in chronic gastritis is the abundance of mucus; the walls of the stomach are covered with it like a blanket so that many times casts of large portions of the stomach walls are found after lavage. The ingested stomach contents are found covered with it, and often balls of mucus, in which are wrapped portions of food, are found among the stomach contents.

The normal motility of the stomach walls is largely destroyed in chronic gastritis. Hence in this respect it is also like cancer, and to this condition is undoubtedly due the abundance of mucus ever present in this condition. The mucus is poured into the stomach, but cannot escape because of the impaired motility of the stomach walls. The stomach is filled with it, its walls are coated by it, and its contents enveloped in it. Hence in chronic gastritis, an examination of the stomach contents is our most valuable diagnostic measure, and we may attribute in no inconsiderable degree the loss of gastric motility in this condition to the action of the superabundant mucus. Normal gastric motility is excited by the presence of ingested substances; coming in contact with the nervous mechanism in the stomach walls, at least it is partially so excited. If mucus so coats the stomach walls that the ingested contents are prevented from coming in contact with these nerve centers, so much of the gastric motility as is due to this is lost. Hence we have formed a vicious circle, the gathered mucus preventing gastric motility, and loss of motility causing large collections of mucus in the stomach.

The well-known beneficial effect of lavage in this condition is undoubtedly due, in a large degree, to the removal of the mucus from the gastric walls, thus rendering the contact between the ingested contents and the nerve centers possible, and by degrees restoring the normal motility of the stomach walls. We know there are cases in this condition in which lavage is ineffectual, but these are cases in which the nerve centers are so impaired by the disease that response to stimuli is impossible.

In gastric ulcer we are forced to recognize the exaggerated motility of the stomach walls as a prominent factor in the differential diagnosis. This is demonstrated by the entire absence in the stomach of any portion of a test meal, even, in many cases, a few moments after its ingestion, the abnormally exaggerated motility of the stomach walls in this condition, contrasting strikingly with the abnormally sluggish action in cancer or chronic gastritis. In hyperchlorhydria and gastric ulcer (the latter being a continuation or culmination of the former, the overactivity of the stomach walls is due to two conditions. First, the ingested gastric contents are quickly prepared for leaving the stomach by the vigorous action of the hyperacid secretion upon it. Second, the vicious action of the overacid and overabundant secretion upon the stomach walls themselves causes a constant and more or less exaggerated contraction of them. In other words, the vicious circle that is ever present in the stomach in this disease, due to the abnormal irritation of the hyperacid secretion upon it, and which in turn causes an outpouring of more secretion, also causes a constant activity of the stomach walls. A test meal deposited in such a stomach is hurriedly ejected from it for the reason that it is immediately emulsified and comes in contact with nerve centers that are on the *qui vive* because of constant irritation. The abnormal motility of the stomach walls thus produced forces the test meal from the stomach quickly in all cases and sometimes almost as soon as it is ingested. If, therefore, we should find the stomach empty an hour or so after a test meal we would be justified in strongly suspecting gastric ulcer, putting all other findings aside.

Mucus is never present in large quantities in this condition, for the reason that as rapidly as it is secreted it is attacked by the abnormal gastric secretion and digested, and it is then no longer mucus, and it is ejected from the stomach almost as quickly as it is deposited in it.

We may, as a rule, refuse a diagnosis of hyperchlorhydria or gastric ulcer if there is much gas fermentation in the stomach. The presence of normal or excessive amounts of hydrochloric acid in the stomach prevents fermentation or putrefaction, and so precludes gas fermentation; but more to the point in this paper is the fact that gas fermentation seldom prevails in a stomach the motility of the walls of which is normal or exaggerated. As the latter conditions universally prevail in these maladies we should not expect to find excessive gas fermentation. Leube says: "As gas fermentation is never found in normal energy of the stomach its demonstration may be considered as a sure proof of motor insufficiency." The above being true, we will seldom find gastric ulcer present in a stomach in which there is excessive gas fermentation.

It is true that we have pyrosis in these conditions which is due to spasmodic contractions of the stomach walls, with the ejection into the esophagus of the hyperacid secretion of the stomach, but this is an entirely different condition from gas fermentation. We believe, however, there is one notable exception to this rule, and that is the gastric neurosis or the so-called nervous dyspepsia. In this condition gas formation in the stomach is preeminently characteristic; whether it is due to fermentation or not may be a question. The diagnosis of this condition rests more firmly upon the fact that the normal motility of the stomach walls is not disturbed in this condition. This is shown by the stomach emptying itself of test meals within normal time limits, or within seven hours from the time of ingestion, and by the presence of large amounts of gas in the stomach.

To Recapitulate.—The loss of gastric motility characterized by long-continued stagnation of food in the stomach, and the partial or complete absence of mucus in the gastric contents, are characteristic of cancer, and when such conditions prevail careful search for the Oppler-Boas bacillus should be made. If this is found the diagnosis of cancer is positive; if it is not found the patient should not be allowed to pass into that stage of the disease in which operative measures are futile, by waiting for this more positive element in the diagnosis before exploratory measures are taken.

A large accumulation of mucus in the stomach is one of the important elements in the diagnosis of chronic gastritis. This is due, in a large degree, to faulty contact between the ingested materials and the nerve centers in the stomach walls causing gastric immotility, which, in turn, prevents the escape of the accumulated mucus into the intestines. The vicious circle being thus formed is broken up in certain cases by long-continued lavage; hence one of the beneficial effects of this treatment in chronic gastritis.

A prominent factor in the diagnosis of gastric ulcer is the exaggerated motility of the gastric walls. This is characterized by the absence of any portion of a test meal in the stomach a comparatively short time after its ingestion. Mucus is also almost or entirely absent from the stomach in this condition, being digested as quickly as deposited in the stomach by the ever-present overacid secretion, and being expelled from the stomach quickly because of the exaggerated motility of the gastric walls.

LUPUS ERYTHEMATOSUS.

By J. PHILLIP KANOKY, M.D.,
KANSAS CITY, MO.
PROFESSOR OF DERMATOLOGY, UNIVERSITY MEDICAL COLLEGE.

Lupus erythematosus, the ulerythema centrifugum of Unna, is a chronic inflammation of the skin, characterized by scaly patches, usually rounded or oval in outline and reddish in color, which are generally followed by scars. These patches may be discrete or confluent, and the face, especially the nasal bridge and upper cheeks, is the region most frequently involved.

The clinical resemblance to lupus vulgaris is often confusing and it was probably for this reason that Cazenave, in 1850, christened the disease "lupus erythematosus." In America it forms about 0.3 per cent. of all skin affections, occurring with about the same frequency as true lupus.

There are two varieties, the local or circumscribed, and the general or disseminated. In the former the disease begins as a small, slightly elevated, flat-topped papule, the bright red color of which does not completely disappear on pressure. This lesion gradually enlarges peripherally until an infiltrated, scaly patch, varying from one to several centimeters in diameter, results, the slightly depressed center of which is studded with the openings of dilated follicles. The scales are of a light yellow or dirty gray color and can be removed by slight friction. The surface of the affected area is always dry, pinkish, or reddish in color, and never ulcerates. At times, after the disease has continued for several months or years, a tendency to spontaneous involution is manifested. In these cases a soft, flexible, permanent atrophic scar is left, the surface of which is marked by the patulous mouths of enlarged sebaceous ducts. A frequent clinical picture is the so-called "butterfly" or "bat's wing" marking. In this type the patches on the upper cheeks have become confluent, a narrow band extending over the bridge of the nose.

The scalp is quite often attacked, permanent loss of hair over the affected area resulting. In this locality the scaliness is less marked and the borders are more elevated than on other parts of the body.

The disseminated variety is seldom seen. The inflammation is more acute in character and is accompanied by constitutional symptoms similar in character to those of erythema multiforme. The lesions may be vesicular or bullous at times. The prognosis is serious, about fifty per cent. proving fatal.

The cause of lupus erythematosus is not known. It occurs most frequently in middle or early life. Several among our foremost authorities believe it to be a form of tuberculosis of the skin, while others, equally prominent, maintain that the two are separate and non-related diseases. Some recent opsonic statistics would seem to indicate that the latter are in the right. From a histopathological standpoint the disease process differs very materially from lupus vulgaris and the tubercle bacilli have never been found in the lesions.

The affection is to be differentiated from acne rosacea, chronic eczema, the syphilides, and true lupus.

In acne rosacea the surface is smooth and glistening, dilated capillaries are a prominent feature, the outline is irregular and ill defined, and the tip of the nose generally shows the greatest degree of involvement. Chronic eczema is seldom if ever dry at all times. Itching is more or less intense, the mouths of the sebaceous ducts are not patulous and do not contain the greasy plugs seen in lupus erythematosus, and there is no formation of cicatrices.

In the nonulcerating syphilide the nodular tubercles, together with the small, depressed, oval or circular, pigmented scars, the duration, the rapidity of evolution, and the absence of dilated follicles will serve for differentiation.

Lupus vulgaris frequently proves confusing. Here the presence of the "apple jelly" nodules, best seen when the areas are examined through a closely applied diascope; the rough, fibrous scars, and the extensive ulceration and tissue destruction are sufficient for recognition. In case of doubt the tuberculin reaction or a biopsy will serve to make clear the diagnosis.

The treatment varies with each particular case. A host of remedies have been recommended, none of which is specific and many seemingly useless. The milder methods and preparations should always receive the first trial. If there are considerable irritation and hyperemia, a soothing application, such as zinc oil (zinc oxide 60.0, olive oil 40.0), or calamine lotion, should be employed for several days, meanwhile administering salicin (commencing with 1.0 gram after each meal and gradually increasing) internally.

If the lesions are in the non-inflammatory, pale, and anemic, I at once paint them with a strong iodine preparation (Churchill's tincture), repeating it three times each week and administering the salicin internally. Here the latter may be alternated with quinine, or the cinchona salt substituted altogether.

Where the induration is marked and the condition notably sluggish, agents possessing marked stimulating power are indicated. I prefer salicylic or pyrogallic acid, suspended in collodion.

℞ Acid. salicylic..... 40.0
Acid. pyrogallic..... 10.0
Collodion 100.0
M. et sig. Shake and apply at night with a camel's hair brush.

If this causes too much irritation it should be temporarily discontinued and one of the soothing preparations substituted.

It is well to look to the general health of the patient. Alcohol, tobacco, tea, and coffee are to be avoided, and foods which have a tendency to increase cutaneous hyperemia should not be eaten. The parts should be kept clean and, unlike the inflamed areas in eczema, the local use of soap and water is not contraindicated. As regards measures other than hygienic and medicinal, the Roentgen ray is not nearly so valuable here as in true lupus and the arc lamp of Finsen has, in my experience, likewise proved disappointing. The liquid air treatment recommended by Fox, Dade, and others would seem an excellent procedure, and the use of carbon dioxide snow, recently suggested by Pusey,

even a better and more practicable course. The latter is certainly deserving of a thorough trial.

During the past eighteen months I have treated five cases of the localized type and seen one case in which the disease was disseminated over the face, trunk, and left arm.

Cases I and II.—Both were railroad men in the employ of the Missouri Pacific, and both have done extremely well under the iodine-quinine line of treatment. In No. 1 the disease was of five years' duration; No. 2 indefinite but had been present for several years. Both were of the typical butterfly type and presented slight scaring. Each case had repeatedly been diagnosed and treated as chronic eczema. At the present time there are no evidences of the disease other than the cicatrices.

Case III.—A married woman of 42, living in Great Bend, Kan. The lesions, which involved the face, forehead, and scalp, had appeared over twelve years prior to my seeing her. This case proved extremely rebellious to treatment. The patches reacted but slightly, even to the applications of Churchill's tincture, so the salicylic-pyrogallic preparation in collodion was substituted. Later, the *x*-ray was employed as an adjuvant measure, twelve minute exposure, with a soft tube, at a distance of 15 centimeters, being given. Internally, salicin was alternated with quinine. Under this regime improvement finally set in and a temporary cure ultimately resulted. Recently she wrote me that a new spot had appeared. I shall try the carbon dioxide snow in this case, although decided benefit resulted from the use of the *x*-ray.

Case IV.—A married woman, 32 years old, living in Kansas City. The disease was of three years' duration and involved both upper cheeks, with an oval patch, about 8x10 centimeters, just below the left temple. In this case the stronger tincture of iodine and the *x*-ray locally, with quinine internally, gave most excellent results. Only a few exposures were given, so the iodine-quinine combination deserves the credit for the splendid and lasting effect secured.

Case V.—A married woman, aged 40, living in Martin City, Mo. The condition had been present for two and one-half years. There was a large oval patch (measuring 8x10 centimeters) over the right eye, an irregular lesion extending across the lower part of the nose, an area about the size of a dime in the interpalpebral space, and slight bilateral involvement of the surfaces lying just above the nasolabial folds. The lesions responded promptly to the iodine applications, although soothing lotions had to be substituted a few times when the inflammation became too intense. Internally, quinine sulphate was alternated with salicin each week. In the course of four months the patches were practically obliterated, and when I last saw the patient, in February, there remained only a slight involvement of the patch over the eye.

Case VI.—This was the case in which the disease was of the diffused or disseminated type. I first saw the patient, a woman, aged 34, in consultation last December, and I have examined her only once or twice since then. The disease commenced on the cheeks; later the left upper arm became involved, and this was followed, a few weeks afterward, by a lesion on the right side of the trunk. The mucous membranes were not affected and the constitutional symptoms were less severe than is usual in this type of the disease. The patient has been receiving only internal treatment, quinine, with phosphorus and other tonics, and appears to be doing well.

Conclusions.—The iodine-quinine, or iodine-salicin, method of treatment, while not infallible, gives excellent results in a considerable percentage of cases of lupus erythematosus, especially if employed early in the disease.

In those cases where the pathological condition has been present for many years these agents will oftentimes have to be supplemented by more vigorous measures. Of these the salicylic-pyrogallic-collodion preparations are cleanly, efficient, cheap, and easily obtained.

The *x*-ray, while not so valuable here as in true lupus, is undoubtedly of assistance at times.

912 Walnut St.

PREPARATION FOR A GENITOURINARY DIAGNOSIS.*

By JULIUS J. VALENTINE, M.D.,

NEW YORK.

ASSISTANT ATTENDING SURGEON, RED CROSS HOSPITAL; ASSISTANT SURGEON, GENITOURINARY DEPARTMENT ST. BARTHOLOMEW'S CLINIC.

A thorough search of literature shows that even the most eminent authors attribute to general practitioners, a familiarity with the preliminary steps necessary to the satisfactory examination of a patient with a genitourinary disease. If this familiarity existed, consultations with the specialist as regards diagnosis would not be needed save in exceptional cases. It would, however, be expecting too much of the general practitioner that he add to his other onerous duties a study of every specialty; moreover, for precision in diagnosis, quite an array of special instruments are required, many of which the general practitioner might need perhaps but once in a life-time. This is particularly the case in the diagnosis of genitourinary diseases. Aside from the expense such aids to diagnosis entail, dexterity in their employment can be acquired only by continuous use.

Another matter which adds importance to the consideration of the patient's preliminary preparation is the fact that the patient usually asks the specialist or his assistants questions regarding diagnosis, prognosis and treatment. It requires exceeding adroitness to avoid specific replies which the layman's unfamiliarity with technical terms may not construe into a variance from his attendant's views. This may engender dissatisfaction with the family physician's conduct of the case, and lead to a general lack of confidence in the medical profession. One example may suffice: If the patient's physician has made a diagnosis of seminal vesiculitis and the specialist, not being aware of the choice of this unfortunate term, calls the disease spermatocystitis, it may be difficult to convince the patient that both are used to designate inflammation of the seminal vesicles. These apparent, not real, differences, are utilized by quacks and advocates of phantastic alleged systems of medicine, to shake the respect due the regular profession. The patient, then, especially one with a chronic genitourinary ailment, is very apt to grasp a to him apparent difference of opinion as evidence of unreliability on part of both attendant and consultant. Indeed, if familiar with German he may then mentally or orally quite ". . . es will mir dünken, als wenn sie alle beide stinken."

The preceding, very coarse outlines seem to justify a recital of the principal steps that are advisable as preparatory to the genitourinary specialist's work.

*Read before the Alumni Association of Internes of the German Hospital in Brooklyn, April 3, 1908.

Conjoint Consultation.—Whenever within the range of possibility, it is desirable that the family physician accompany the patient. Individual idiosyncrasies are then easily explained, important points of general and special history, that might escape the patient's mind, are more easily recalled by his medical attendant in the patient's presence; matters of technique in examination and treatment with which the physician may not be familiar can be demonstrated to him far better than possible in a written report alone.

The family physician's presence is further important in what may appear a minor matter, namely that of language. It is true that the cosmopolitan population of our large cities has necessarily made the majority of genitourinary specialists at least conversational masters of several languages. They were prepared therefor by their studies of German and French text-books on the specialty. But without the family physician's presence the patient's expressions may lead, not infrequently, to serious misapprehensions. For demonstration the following will serve: A patient reports frequent "night-sweats" when he means seminal emissions; another speaks of pain in his "molar," when he means the penis; still another asks for relief from his "reflexes," alluding to the discomfort in the glans due to prostatism. One patient astounded our entire staff by asserting, so far in advance of the times, that he had been treated by the surgeon of a "Luftballon." His physician, who was present, explained that an ambulance was meant. The misemployment of terms, technical or other, is not confined, however, to the ignorant classes. Thus one educated gentleman, giving his history, calmly reported an escape of prostatic juice "every time I remove my bowels." In this case, naturally, the presence of his physician was not needed to make clear the patient's meaning.

The History of the Case.—Many general practitioners, appreciating its value in the study of the case, send with their patients a record of the genitourinary history. For as great perfection as may be possible, a general family and personal history is almost equally important. It may reveal, in perhaps a patient with apparently superior resistance, a tuberculous, neurotic or rheumatic trend, against whose possibilities he must be safeguarded as much as may be in the physician's power.

Some physicians, attributing to the specialist abilities far greater than human, write, if they write at all, "please examine Mr. ———" and thus leave the consultant exposed to all the possible errors due to the patient's defective memory, and the embarrassment natural to many on reciting their genitourinary ailments to a stranger.

The Time of Consultation.—The patient and the specialist are often equally inconvenienced by the former being sent for consultation without a previously-made appointment. Assuming, for illustration, that the specialist has only ten appointments for a given day, and that a patient arrives for examination at 9 A. M. on that day, without an appointment. Each genitourinary patient requires no less than 45 minutes when under treatment; new cases to be examined must be given at least one and a half to two hours each. When, however, a case presents tight, tortuous strictures that must be explored, or there is a cystoscopy to be performed, or ureters catheterized, the examination may be protracted to three hours or more. As these cases, however, are usually deferred to the days which the specialist reserves for such purposes, the basis of only ten appointments may be used to illustrate the more ordinary conditions. The patient, let us call him Mr. A., arrives at 9:15 A. M., with perhaps nothing but his physician's card as a guide. Mr. A. is a very busy man and has been told, quite correctly, that his physician is a personal friend of the specialist. Mr. A. then naturally expects that he will receive very prompt attention. The specialist, however, is bound by his appointments, only ten for that day, each one requiring an average of 45 minutes. Mr. A.'s turn would arrive in nine hours, provided the specialist took no time for luncheon and was not interrupted in his work by from fifteen to thirty telephone calls or other urgent communications during that time. Even if Mr. A. is not an irritable or even impatient gentleman, he is not likely to await his turn. He may not even be willing to defer his examination to the appointment that can be made for him, but may inform his physician that he will find another medical man to attend him who will refer him to a specialist from whom he will receive prompt attention. Mr. A. may be an important man in his community and consequently have a following that is professionally useful and lucrative to his physician. The physician, not unnaturally, will resent the loss of the patient. It is thus that lifelong friendships between general practitioner and specialist are sometimes broken, merely by the omission of the former to arrange an appointment for his patient.

Emergencies, of course, such as retention of urine, as occur with the strictured and prostatics; vesical or renal hemorrhages, passage of kidney stones; or cases requiring immediate capital operations, must take precedence over all others, and consequently do not come within the above category.

Preliminary Instructions to the Patient.—The patient should be directed to pass no urine for three or four hours before visiting the specialist. Then only, can the amount and character of the discharge, if there is any, be studied to the fullest advantage, and specimens for microscopy and culture be secured. The macroscopic character of the urine can then be studied, and the specimens therefrom saved in suitable condition for chemical and microscopical examination.

Naturally this restriction does not apply in acute cystitis, posterior urethritis, the genitourinary neuroses, or other conditions that make frequent or excessive urination imperative. The object in view can in such cases be best attained by asking the patient to present himself an hour or two before the time for his examination, during which the urine can be gathered in tubes and other valuable observations made under the consultant's directions, while the time is given to other patients.

The ideal appointment for examination of a patient with chronic gonorrhea is before he has passed his first urine in the morning. The reason therefor lies in the fact that the morning drop or filament or two in the first urine may be the only manifestation of disease, in some cases. No gonococci may be discoverable except in that drop or filament.

Unfortunately the patient who can come for consultation before he has urinated, is exceptional; the only exception being in those cases that are sent from a distance for examination. These will generally be found able to cooperate with the consultant in this respect. These may often have been sent for an opinion as to the permissibility or otherwise of marriage, because of a gonorrhea which has left no vestiges externally evident.

While it is not absolutely necessary that a patient be brought for consultation with an empty rec-

tum, it is advisable that he be instructed to relieve himself not more remotely than several hours before the time appointed for his examination. Then the inevitably unesthetic character of digital exploration of the prostate and seminal vesicles will not be exaggerated by the presence of fecal masses, and the attention of the finger in the rectum will not be diverted from its purpose.

The exceedingly rudimentary character of this paper finds its justification in practice. Therefore no apology is offered except for the crudities of presentation. In the hope that this effort may be made useful through the discussion with which it may be favored, the following summary is submitted:

1. The general practitioner cannot be expected to incur the expense of the large number of instruments required for genitourinary diagnosis.
2. To use special instruments effectively, continuous practice is essential.
3. The average layman's unfamiliarity with technical terms may lead to an assumption of error in diagnosis on part of his attending physican, if the specialist's designation for the same condition should be a different one.
4. Conjoint examination by the physician and specialist is always desirable.
5. The history of the case presented by the physician is always of more assistance than that given by the patient.
6. Appointments for consultation should always be made as many days in advance as possible, so that the time set aside for the purpose can be devoted entirely to that patient.
7. The patient should be instructed to refrain from urinating for as long a time as possible before the hour of consultation.
8. The patient should be advised to empty his bowels as shortly before consultation as possible.

171 West Seventy-first Street.

A KERATOPLASTY.

By HENRY R. LESSER, M. D.,

NEW YORK.

The transplantation of the cornea of a rabbit to the human eye, with retention of transparency, is a procedure about which the literature is exceedingly meager. I have been able to find but one article published recently, that of Dr. Francis Valk, in the *American Journal of Surgery*, January, 1908, and I am indebted to Dr. L. W. Fox for a reprint of his report, published in the *Medical and Surgical Reporter*, July 21, 1888.

The case I have to submit is my first, and the results are so extremely gratifying I am determined to perform the operation as often as I can find suitable material.

The patient is a young man of 24 years, blinded through measles at the age of 9. The right eye is entirely useless; the left eye presented a dense leucoma, covering almost the entire cornea, but densest in the center.

Vision, none; light perception and projection good.

When the patient applied to me for relief, I explained the possibilities of the operation to him and immediately obtained his consent. I placed him on one grain of mercury with chalk three times a day for two days prior to the operation, and bandaged the eye with a 1/2000 bichloride dressing the night before. The rabbit used was 8 months old.

The eye having been irrigated and cocainized, a von Hippel trephine was adjusted and an incision made down to Descemet's membrane. The disc was then carefully dissected off. For this purpose I used a curved iris forceps and an angular keratome. The membrane of Descemet was found to be transparent.

The trephine was then applied to the rabbit's eye, and a disc removed from the cornea, including Descemet's membrane. This was swiftly carried to the patient's eye, and inserted into place by a delicate glass rod passed through the tube of the trephine.

When the graft was nicely fitted, the lids were closed and a pressure bandage adjusted. This was allowed to remain for forty-eight hours, when the eye was opened, and the graft found to be solidly in place and slightly hazy. I then inserted a glass conform between the lids and eyeball, preventing undue pressure and minimizing the danger of disturbing the graft when separating the lids subsequently.

This was removed on the sixth day, when it was found that there were two small blood-vessels extending over the cornea and graft. These subsequently disappeared of their own accord, and at the present writing, three months after the operation, the graft is in perfect apposition. The vision is improved to the extent of counting fingers at twelve inches. Patient distinguishes objects well enough to get around with little or no trouble, and he tells me he is beginning to "learn colors again."

The graft is only slightly hazy, and seems gradually to be clearing. Whether this will retain its comparative transparency, or gradually become opaque, remains to be seen. But, in the words of the patient, "even if it only lasts a few months, it will have been worth while."

From the results of this one case I am convinced of the possibilities for this operation, and I shall, I repeat, continue to perform it on all available cases, hoping in the future to be able to render a fuller and more comprehensive report.

14 West Ninety-third Street.

Relation of Mycosis Fungoides to Infection and Malignancy.—F. G. Bushnell and A. W. Williams note that the relation of mycosis fungoides to the infectious granulomata is seen in (1) the diffuseness and absence of capsule formation of the growth; (2) the presence of lymphoid cells which resemble the proliferating cells and lymph follicles, of plasma cells, and of mast cells, as seen in the granulomata; (3) the numerous thin-walled vessels; (4) the necrosis of large areas of growth. The relation of mycosis fungoides to sarcomatosis is seen in (1) the rapidly fatal course, when once evolutionary tumor formation supervenes (the duration of the disease being ten or twelve years in our case, and the evolutionary stage four months—a "malignant granuloma"); (2) the bulk of the tumors, and the arrangement of cells and fibers as in lymphosarcoma; (3) the presence of metastases in brain, kidneys, adrenals, retroperitoneal glands, dura mater, liver, and spleen in recorded cases; (4) the close relation that exists between leucorrhea, infectious follicular vaginitis, balanitis, and lymphoid sarcomata of bitches, and its parallel in this disease and the diffuse character and malignant course of the lymphomata (lymphocythemia). Here it may be noted that persistent dermatitis is the precursor of "Paget's disease" (carcinoma of breast, scrotum, vulva and umbilicus), and that lobulated warty condylomata of dogs arise from irritation. There is a clear resemblance of mycosis fungoides, despite its inflammatory structure, to "infectious sarcoma" of dogs. The latter is characterized by the presence of uniformly large, round, pale staining mononucleated cells with nucleoli, not arranged as alveoli, but in cords or diffuse areas; the blood-vessels are moderately developed. The surrounding tissue is displaced outwards, and is free from signs of inflammation. Large areas may necrose. It is highly infectious, produces metastases, and the transference of living cells is necessary to secure growth.—*British Medical Journal.*

MEDICAL RECORD.

New York, September 12, 1908.

NEW DATA IN THE STUDY OF DIABETES.

THE modern study of the pathogenesis of diabetes may be dated from the experiments of Minkowksi who showed that the loss of the pancreas in dogs leads to the appearance of a hyperglykemia and a glycosuria. Immediately there was postulated the theory of the internal secretion of the pancreas which had to do with sugar metabolism and therefore played an important rôle in the pathogenesis of human diabetes. Ever since, research workers have endeavored to discover this hypothetical internal secretion with the hope of thus explaining the mystery of a frequent and serious disease of metabolism. Lepine thought he had obtained a glycolitic ferment from the pancreas and lately Cohnheim has described a similar substance obtained by the union of the juice of muscles with an extract of the pancreas. Neither experimenter could wholly substantiate his claims and other workers have continued the search for the supposed internal secretion of the organ. F. Blum has shown that hyperglykemia as well as glycosuria follows the injection of the active substances of the adrenal gland into animals, and G. Zuelzer in company with Dohrn and Marxer has used this observation as a starting point in his experimental study of diabetes (*Deutsche medizinische Wochenschrift*, August 6, 1908). The latter showed that transfusion through the liver of a dog killed at the height of the "adrenalin diabetes" leads to a marked rise in the sugar content of the transfused blood. These results led to the hypothesis that the liver is the organ in which the adrenalin and the mysterious internal secretion normally meet, their union preventing the excretion of sugar in the urine. It had seemed as if the adrenal substances were capable of "mobilizing" the sugar from the liver or from other organs or perhaps could lead to an increased formation of sugar from the elements contained in the protoplasm of the parenchymal cells of these organs. Further evidence in favor of the view of the combined action of pancreas extract and adrenal substances was given when Zuelzer succeeded in preventing the appearance of an "adrenal diabetes" by a simultaneous injection of the two substances.

Starling has lately developed the theory of "hormones" or substances which upon reaching an organ act as stimulants to its secretory activity, thus connecting the functions of one set of organs with another and producing harmony in the results of their various activities. Such a hormone is *secretin* which stimulates the secretory activity of the pancreas when it reaches that organ by way of the blood. It is possible that some similar substances may be obtained from animal organs that will stimulate the internal secretion of the pancreas concerned with the production of sugar and thus the course of diabetes may be influenced. Zuelzer has endeavored to follow this suggestion of the English physiologist and has obtained a pancreas extract which is capable of diminishing or preventing the specific effect of adrenalin upon the sugar production as well as of affecting quite favorably the diabetes of depancreatized dogs. Still more interesting results were obtained in several cases of actual or threatening diabetic coma in human beings, the injection of the new preparation showing that it is capable of affecting the symptoms of this serious complication of diabetes in a manner which leaves little doubt of the specificity of its action.

It is probable that the group of symptoms which we classify under the one name "diabetes" has a varied etiology. That organic or functional disease of the pancreas is responsible for a great many cases of this affection can no longer be doubted and the results obtained by Zuelzer and his collaborators encourage the hope that not only the explanation of the relation between disease of the pancreas and the origin of diabetes will soon be discovered but in addition the therapy of this special form of the disturbance of carbohydrate metabolism will be put upon a rational scientific basis.

THE PSYCHOLOGY OF SUCCESS.

THE problem of the underlying factors making for success or failure in life is one that has puzzled the sociologist, the theologian, and the common man for ages and promises to give food for cogitation for ages yet to come. The belief in Divine favor is a flattering one to the man who has succeeded, though many such a one, if he would accept this theory, must in his inmost soul confess that the Lord "moves in a mysterious way His wonders to perform." Neither does hard, conscientious work always bring the reward of success. Many a man of good average ability has spent his soul in faithful work, never rising above mediocrity and a meager salary. Brilliancy akin to genius is often surpassed by mediocrity, if not actual stupidity. Of course, in a discussion of success, the term must first be defined. Many an obscure toiler is content with his lot and accounts himself happy. Such a man may have achieved success in his own estimation but not in the eyes of the world. In a lecture on the "Psychology of Success" delivered on June 30 by Dr. Thomas Claye Shaw, a British alienist, before the Medical Graduates' College and Polyclinic of London, the speaker defined success as "the accomplishment, the realization, of what has been willed or wanted, the ripe fruition of the well tended tree," but in his development of the argument as to what works for "success" he showed that this was not a complete definition of what he had in mind. What he really meant was the achievement of fame or fortune, and this is what the world in general regards as success.

In the first instance the speaker declared that he was not a believer in what is known as luck, al-

though perhaps he defined luck somewhat ambiguously. He said that "Nobody wins when he ought not to do so, but he may win when he did not expect to do so. To be lucky is to succeed when you did not expect to succeed, and should not have succeeded, when you have unconsciously tumbled into the path which leads to success. To be unlucky is to find yourself placed in circumstances which are against a favorable issue, but which are a necessary result of the 'content' of causes, some of which were either ignored or were not valid for your consciousness."

It is acknowledged, he said, that some of the most important parts of the mental content that make for success are cruelty, sacrifice of others, and deceit. Dr. Shaw thinks that this cannot be avoided and that a strong man is generally a ruthless man who tramples his way to the goal of his endeavor. Although every one professes to admire virtue, charity, and courtesy towards others, these very qualities are often the outward and visible signs of incapacity. Again, some individuals are constitutionally and by temperament virtuous, that is to say they have no temptation to err, and such are not the successful ones. Courage is also an essential factor in the achievement of success in any undertaking. The modern tendency towards advertising is regarded with lenient eyes by this authority, who argues as follows: "How can recognition of merit be expected unless it is known to exist and the public be made to believe in it? So, practically, the arbiter of success is the public; therefore, the only way to get at the public is to advertise. But this has to be done carefully, and the legitimate paths for it are few and very jealously guarded. Perhaps there is more laxity in considering the bounds of legitimate advertising than was permitted some time ago, and much is to be said for the propriety of taking the public into professional confidence."

Dr. Shaw seems to be somewhat in favor of the view that so generally prevails—succeed honestly if possible, but at any rate, succeed. This is not a pleasant conception of the mental and moral make-up of the successful man, and it is more comforting to believe that there are many successful men in the world who would gladly have foregone "success" rather than purchase it at such cost.

THE NEED FOR NEW HOSPITALS IN NEW YORK CITY.

An interesting summary and report on the present condition and future needs of hospitals in Greater New York has been published by the Standing Committee on Hospitals of the State Charities Aid Association. As the population of the city has increased there has been a growing demand for more complete and accurate knowledge of the work and needs of those institutions charged with caring for the sick. This is now furnished in pamphlet form and is calculated as far ahead as 1920. The number of sick in a given district has been estimated from the records obtained by the police and the hospitals themselves, and an attempt has been made to show how well such district is served. While this is satisfactory enough, perhaps, for determining the number of people who are using a given hospital, it by no means covers the number who are being treated at home, who are ill but without treatment, or who might make use of a hospital if it was more accessible or if they were confident of a high quality of service.

It may be said that the need is not for more hospitals, but for better organization and systematization of what we now have. For instance, on March 1 a certain institution with 216 beds accommodated only 161 patients, but 7 extra cots were in the surgical wards while 20 patients were clamoring for admission to the surgical service. This shows not a lack of beds, but that something is vitally wrong with the system. A level-headed business man would clean out a medical ward or two and put into it the surgical convalescents and those not seriously ill or not infected with pus organisms. By this means it would be possible to use the institution to pretty nearly its full capacity. In many hospitals the barrier between the medical and surgical sides is impassable. This is always undesirable and usually unnecessary. A house divided against itself cannot stand.

The modern hospital is becoming a business enterprise with a set purpose of making it pay. There is the same competition, jealousy of district boundaries, of quality and quantity of work done that there would be in a purely money-making institution. Every superintendent must make a good showing, and is obliged from the day of his incumbency to stare at the specter of annual report and statistical summary with misgivings lest it may not look quite as well as that of last year. Consequently there is a constant temptation to see to it that as few patients as possible die in the house. Bellevue is the place for patients fatally ill, and there he must send them.

Any recommendations for the building of new hospitals must take into account that the general practitioner is likely to be adversely affected thereby. People are coming to find out that the best and cheapest doctors have hospital connections. A dollar a day in a ward with Professor So-and-so as their adviser appeals to their economic sense. The professor cannot stop to reflect that it is a hardship for the youthful physician to lose control of his case because he is not on the attending staff of the hospital.

The abuse of dispensary privileges, concerning which so much has been written, will probably always obtain. It is not possible to keep the original purposes of a hospital within bounds, viz., to care for the sick poor primarily, for the well-to-do incidentally, and for both well-to-do and poor upon any sudden necessary demand. The time may yet come when all patients who can get there by any means will go to hospitals for treatment, and house to house practice will be largely a thing of the past. This would be a distinct advantage to the physician, who could have most of his patients under one roof, but a very different matter for the physician who cannot, who, without any organization behind him, must depend upon the vagaries of a shifting population for the earning and the payment of his fees. How to distribute the greatest amount of good among the greatest number, both of laymen and physicians, will always be the chief problem of hospital construction and management.

TOXIC TUBERCULIDS—PARATUBERCULOSIS.

The well-known fact that in many skin and glandular lesions of tuberculosis it is not always possible to demonstrate the bacilli of the disease has usually been explained by the assumption that very few bacilli were responsible for the appearance of these lesions; the negative result of the inoculation of animals with such material was explained by supposing that the bacilli causing the local disease had either perished or had become almost nonvirulent after their struggle with the local defenses of the organism. In the *Münchener medizinische Wochenschrift* for August 11, 1908, Dr. Karl Zieler revives another explanation for these facts, namely, that the lesions in question are caused by soluble and diffusible products of the tubercle bacilli, that is, by true toxins and not necessarily by the endotoxins of the bacterial bodies. This causation which, of course, is well proved for such diseases as diphtheria, in which the toxins of the disease can produce all the lesions and the general symptoms of the affection, has been questioned so far as tuberculosis is concerned because of the accepted notion that the poisons produced by the tubercle bacilli are not to be ranked with the true toxins such as those of tetanus or of diphtheria.

Zieler has experimented with a tuberculin which was conclusively proved to have been free from any dead bacilli or particles of their bodies, centrifuging experiments and ultramicroscopic examinations being negative. Substances obtained by dialyzing cultures of tubercle bacilli were also used, and in several cases in which it was possible to examine microscopically the lesions produced by the injection of these tuberculins the picture was similar to those of the usual classical descriptions of tuberculous lesions. The infiltration of the tissues with epithelioid cells, the presence of the giant cells of the Langhans type, the areas of necrosis or caseation, were all there to make up the complete structure of a tubercle.

These results are not in agreement with the views of such workers as Wolff-Eisner and von Pirquet who look upon the action of tuberculin as due wholly to the bacterial *débris* contained in it, that is to the endotoxins liberated by the destruction of the bacilli in their growth or in the process of preparing the substance. The experimental evidence adduced by Zieler seems strong enough, however, to prove the correctness of his standpoint; the truth one way or the other can have presumably little practical significance, but the understanding of the development of tuberculous lesions is much furthered by the findings reported above.

Lateral Curvature Among School Children.

The treatment of scoliosis has run the gamut from the time when these unfortunate persons were placed in a rigid support, which still further weakened their already flaccid muscles, through the various forms of exercises used for developing the spinal muscles, to the present day when Fernand Lagrange, writing in the *Archives de Médecine et des Enfants*, for July, 1908, tells us that the first principle in treatment should be rest for the spinal muscles, and that the exercises that are initiated later should be only such as shall be educative of the muscles, and not at all violent. Lagrange shows that scoliosis is very frequent among French school children, who are obliged to sit for many hours each day on benches that have no support for the back or arms. He also finds the difficulty present among young men and women who work in factories for long hours in a sitting position. Such a position keeps the muscles of the back continually on the stretch, and in one position. The young individual is less able than the grown man to maintain the same position for a long time, while he is better able to make repeated rapid movements. The result on the young patient of the strain of sitting is that he tries to rest his muscles in some way. If standing he rests on one foot, if sitting he rests on one hip. In this way he produces and maintains the position of scoliosis as a position of rest, and the muscles of one side become weakened in proportion. This, Lagrange maintains, is the principal factor in the production of scoliosis in young subjects. The strong are not affected, while the weak or predisposed acquire a permanent curvature of the spine. This matter has received considerable attention in connection with Medical School Inspection in our own city, and a systematic examination of the spines of all school children has been made for several years, the proper treatment being urged upon the parents. Exercises have also been introduced into the schools to vary the monotony of the long periods of sitting. It should not be forgotten, however, that an occasional, according to Gould the usual, cause of lateral curvature of the spine is some defect in refraction which forces the child to hold the head to one side in order to see clearly.

The Cause of Whooping-cough.

That whooping-cough is an infectious disease caused by some specific microorganism has been the common belief among physicians ever since the microbic theory of diseases was firmly established. None of the many germs, however, that have been described by various observers, could be finally proved as the specific excitant of the infection in question, until Bordet and Gengou published their report on the bacteriology of pertussis in the year 1906 (*Annales de l'Institut Pasteur*, page 731, 1906). They found a rod-like organism, that was Gram-negative in staining properties, required blood elements in the culture media, and could be easily differentiated from the influenza bacillus and other common inhabitants of the pharynx. Many bacteriologists have since corroborated the findings of Bordet and Gengou, among them C. Fraenkel, who reports his work in the *Münchener medizinische Wochenschrift* for August 11, 1908. He has succeeded in cultivating the organism described in eight cases, failing to do so in thirty others: this large percentage of failures is explained, however, by the fact observel by Bordet and Gengou that the bacterium of pertussis is present in large numbers and almost in pure culture in the early stages of the disease, and is very hard to find or identify later, when the mouth and throat become the seat of mixed infection with a great many other bacteria. The organism proved pathogenic for animals, producing death in guinea pigs and rabbits. Of especial interest were the results obtained with apes: when exposed to germ-bearing dust the animals fell sick in five or six days, the disease closely simulating in symptomatology the usual picture of

whooping-cough in human beings. Dr. Fraenkel declares that personally he is quite persuaded that the organism discovered by Bordet and Gengou is the excitant of pertussis; he urges other workers, however, to take up the study of the bacteriology of pertussis, so that the germ may be surely identified, and the diagnosis of the disease in early stages be put upon a firm scientific basis.

Parenchymatous Injections of Protiodide of Mercury in Syphilis.

The methods of administration of mercury for syphilis have been much improved of late years over the old uncleanly mercurial inunctions. The use of intramuscular injections of insoluble salts of mercury gives much more rapid results, besides avoiding the symptoms of gastrointestinal irritation and salivation that have been the great drawbacks to the use of this drug as a specific, and have rendered necessary considerable periods of intermission in its administration. The protiodide has always been a popular form of the drug for administration by mouth. In 1902 Levy-Bing reported six cases of syphilis treated by intramuscular injections of this salt, recommending it as well tolerated, producing no bad effects and no pain after injection, while its therapeutic action against the secondary and tertiary lesions was rapid and marked. Pietro Stanconelli reports in the *Giornale Internazionale delle Scienze Mediche*, June 15, 1908, a new series of cases of severe forms of syphilis that had been rebellious to other mercurial salts, treated with marked success by intramuscular injections of the protiodide in suspension in sterile vaseline, in the proportion of one to ten. Of this suspension the dose contains ten centigrams of the protiodide, and the injection is repeated every fifth day. He confirms the statements of Levy-Bing that the salt is well tolerated, acts rapidly, and is especially effective in the secondary stage of the disease. From two to six injections will cause complete regression of the eruptions.

News of the Week.

Tuberculosis in Chicago Hospital.—The contract for the erection of the new hospital for tuberculosis on the grounds of the Cook County Hospital (Illinois) has been let and awarded for $222,900 to the lowest bidder. This new building will be five stories in height, 162 feet long, with three wings, each 128 feet long, and will accommodate 320 patients.

Rules for Tuberculous Travelers.—According to orders issued by the Lehigh Valley Railroad Company all consumptives traveling on its trains must provide themselves with sputum receptacles and private drinking cups. This order was issued in response to a request of the Pennsylvania Society for the Prevention of Tuberculosis that the railroad companies aid in stamping out tuberculosis by protecting travelers from danger of infection by the carelessness of known victims of the disease.

Summer Care of Babies.—Dr. Walter Bensel, chairman of the conference on summer care of babies, has sent a letter to each of the fifty public and private agencies that belong to the conference summarizing the work of the three summer months. The largest number of nurses employed was 83, of inspectors, 20. All told, 26,075 mothers were interviewed and instructed in their homes; 8,747 revisits were made; 4,926 instructions were given to mothers on piers; 318 lectures were given in ninety-two schools; instructions were given to mothers attending 318 school lectures, for which an attendance of 10,878 is recorded; sick babies received 1,372 visits at their homes; 1,071 treatments were given sick babies on piers, while 361 treatments were given to sick babies brought to school lectures.

Labor Unions Fighting Tuberculosis.—A pavilion for the care of patients with tuberculosis was formally dedicated, on August 29, on McCarthy avenue and Brown street, on the outskirts of Albany. The pavilion was built by the Albany Federation of Labor to aid those interested in the campaign that is being waged in this State against tuberculosis. Among those who participated in the ceremonies were Governor Hughes, Secretary of State John S. Whalen, and Homer Folk, Secretary of the State Charities Aid Association.

Bequests to Charities.—By the will of the late Levi Mayer of Philadelphia, the following bequests are made: Jewish Hospital Association, $2,000; United Hebrew Charities, $1,000; Jewish Maternity Association, $200; Pennsylvania Hospital, $100. In addition to a bequest of $2,000,000 to the New York Post-Graduate School and $500,000 to Yale University, Mr. Frederick Cooper Hewitt of Owego, N. Y., left $200,000 to the Little Missionary Day Nursery, New York; $100,000 to the Free School for Crippled Children, New York; $100,000 to the Netherwood (N. J.) Fresh Air Home; $10,000 to the American Society for the Prevention of Cruelty to Animals, New York; $10,000 to the Sheltering Arms Society, New York.

Death of a Centenarian.—Mrs. Una Carr died at Pottsville, Pa., on August 25, at the age of 105 years. She was born in Ireland and came to the United States when the only means of conveyance between Philadelphia and Pottsville was a stage-coach.

The International Congress on Tuberculosis will be held, as previously announced, in Washington, D. C., from September 21 to October 12, 1908. The actual scientific work of the sections and the general sessions will occupy the week from September 28 to October 3. Every physician interested in the subject is urged to become a member of the congress and to send his name and address together with the fee of five dollars for active membership, or three dollars for associate membership, to the Secretary-General, Dr. John S. Fulton, Washington, D. C. Dr. Charles Wood Fassett, of St. Joseph, Mo., is organizing a party of members or associates of the Missouri Valley Medical Association, who will leave St. Louis on September 26 in a special train.

Dr. S. Weir Mitchell of Philadelphia has been elected a foreign Fellow of the Royal Society of England. Benjamin Franklin was the first American to be elected a member. Only three Americans are now carried on its roll—Alexander Agassiz, George W. Hill, and Simon Newcomb.

Tabitha Hospital, Lincoln, Neb., was dedicated with appropriate ceremonies on Friday of last week. The hospital is under the control of the Evangelical Lutheran Church of the United States. The hospital will accommodate one hundred patients.

Trinidad Declared Free from Plague.—On the receipt of a telegram from the Dutch Consul at

Port of Spain, Trinidad, declaring that the sanitary situation at Port of Spain was excellent, the Government of Curacao recently removed the quarantine that was declared against Trinidad some time ago because of the bubonic plague. This step was taken in spite of the receipt of private letters from Port of Spain declaring that a bacteriological examination of rats there showed the existence of the plague among the animals.

Porto Rico Anemia Commission.—The House of Delegates of Porto Rico was called to meet in extra session on September 8 to consider, among other things, the recommendations of the Governor for the continuance of the Anemia Commission which has done such effective work looking to the supression of uncinariasis.

New York State Veterinary Medical Society.—At the annual meeting of this society, held in Utica last week, the following officers were elected: *President,* Dr. Robert Ellis of New York; *Vice-President,* Dr. Walter C. Hollingsworth of Utica; *Secretary-Treasurer,* Dr. J. Devine of Goshen; *Censors,* Dr. G. H. Berns of Brooklyn, Dr. W. L. Williams of Ithaca, Dr. F. D. Holford of Sidney, Dr. W. H. Phyfe of Chatham, and Dr. R. C. Reed of Elmira. The next annual meeting will be held in Ithaca.

A Plague Conference on the Pacific Coast.—Invitations have been issued by Dr. Spiro Sargentich, Health Commissioner of Tacoma, Wash., to all the health officers of the Pacific Coast cities to attend a conference in Tacoma for a discussion of the bubonic plague and of the means for combating it. A number of physicians of the coast cities as well as the health officers have signified their desire to attend the conference. It is believed the conference will result in the boards of health in all coast cities uniting in a vigorous campaign against rats, and will recommend the adoption of more stringent sanitary measures.

American Public Health Association.—At the meeting of this association at Winnipeg the last week in August, the following officers were elected: *President,* Dr. Gardner T. Swarts of Providence, R. I.; *Vice-Presidents,* Dr. R. I. Simpson of Winnipeg, Jesus Chico of Mexico City, and Charles F. Mason, U. S. A.; *Secretary,* Dr. Charles O. Probst of Columbus, Ohio; *Treasurer,* Dr. Frank W. Wright of New Haven, Conn. The next meeting will be held in Richmond, Va., in 1909.

New York Dispensary.—Plans for the new building of this dispensary have been filed. The new edifice, which is to cost $25,000, will be 50 feet front and 96½ feet deep, one-story and basement, in the style of the Italian Renaissance palaces, with a large central doorway finished with a decorated arch of marble and terra-cotta, supported by Cornithian columns and flanked with windows similarly arched and adorned. The building will be lighted by a dome ceiling of paneled glass. The façade will be of brick trimmed with bluestone and terra-cotta, and having an ornate cornice of terra-cotta work.

Superintendent Wanted for Craig Colony.—The Civil Service Commission of New York State announces an examination to be held on September 26 for the position, among others, of Medical Superintendent of Craig Colony for Epileptics at Sonyea. The salary attached to the position is from $3,500 to $4,500 per annum and maintenance. The vacancy has been created by the resignation of Dr. Spratling who is going to Baltimore to become a member of the Faculty of the College of Physicians and Surgeons in that city.

Phonograph Lectures on Tuberculosis.—At each of the New York county fairs visited by one of the tuberculosis exhibitions of the State Charities Aid Association a large talking machine is to be used in connection with the exhibition. The people will hear a voice telling them in solemn tones that in this country every day throughout the year over 400 lives are yielded up in tribute to the great white plague, more than were lost at the Iroquois Theater fire several years ago, and it will tell them that most of these deaths from the disease were unnecessary. The voice will tell them how the disease spreads, under what conditions it is most prevalent. It will warn the inhabitants of the rural districts that to nail their window shut is to drive a nail into their coffin. They will be asked to throw open the close, shut up parlor which is used only for an occasion like a wedding or a funeral—to let in the fresh air and blessed sunshine even though it does fade the carpets. They will be reminded that it is much better to let the carpets become faded than to allow the bloom to fade on the cheeks of their children. They will be told how the disease may be cured, how it may be prevented. Selections from comic operas and popular airs will be interspersed to amuse the visitors to the exhibition and tempt them to stay to listen to the serious talk.

The National Medical Association, an organization of negro physicians, dentists, and pharmacists, held its annual meeting in this city during the last week of August. Dr. P. A. Johnson of New York was elected president for the coming year. The next meeting will be held in Boston in the summer of 1909.

Gift to the Post-Graduate Hospital.—Mr. Frederick Cooper Hewitt, who died in Owego, N. Y., on August 30, left by his will $2,000,000 to the New York Post-Graduate Hospital and Medical School.

Public School for the Deaf and Dumb.—The first school for the instruction of deaf mutes in the New York public school system will be opened on September 14 at 225 East Twenty-third street, the building until recently given over to the Stuyvesant High School. The institution, which will comprise twenty-five classes, is intended for mute children from all the boroughs. The object of the school is to prepare children with a three-year course, so that at the end of that time they may be able to enter the regular classes of the schools and in spite of their physical handicap benefit by the general instruction.

Guaranteed Oysters.—The new section of the Sanitary Code provides that oysters that have been fattened in polluted waters cannot be sold in this city, a direct trip of the oyster from ocean to market being demanded. The new law requires that every person who sells oysters in this city must have a written permit from the Board of Health. All applicants are required to give the names of the growers from whom they buy their stock and the location of the beds. The permits are revocable on proof that a dealer is selling "drinked" oysters, as the oystermen call them—that is, oysters that have been fattened in polluted waters. During the summer officials of the Health Department have inspected all the oyster beds from this city to New Haven and down the New Jersey coast as far as Manasquan, and, according to the assurance of the health

officials, New Yorkers may consume the city's supply without the slightest fear that the oysters may have come from contaminated beds.

Alcohol and Climate.—In an address before the Anthropological Section of the British Association for the Advancement of Science, meeting in Dublin last week, Professor Ridgeway asseverated that no attempt to eradicate the tendency to imbibe alcohol in northern latitudes could succeed, because the universal love of strong drink there was not the mere outcome of vicious desires but of climatic law. Philanthropists and legislators could not do any more than control it.

Obituary Notes.—Dr. William Baer Woods of Somers, Mass., died on August 25 at the age of 89 years. He was born in Belchertown and was graduated from the Berkshire Medical College in 1841. He served for a time during the Civil War as surgeon to a Connecticut volunteer regiment.

Dr. James Clifford Kennedy of Pittsburg, Pa., died on August 25 at the age of 75 years. He was originally connected with the Pennsylvania Canal, and later served in the Civil War in the 63d Pennsylvania Volunteers. At the close of the war he studied medicine, graduating from the Hahnemann Medical College of Philadelphia in 1871.

Dr. Elbert F. Nebecker of Danville, Ill., died on August 29 at the age of 38 years. He was born in Covington, Ind., and was graduated in medicine in Chicago in 1906.

Dr. Josiah Fisher Day, a retired physician of Malden, Mass., died in Everett on August 22 at the age of 75 years.

Dr. Titus Albright of Norristown, Pa., died of typhoid fever on August 30, at the age of 48 years. He was born at Hilltown, Berks County, Pa., and was a graduate of the Medical Department of the University of Pennsylvania.

Dr. Jacob Farnum Holt of Philadelphia died on August 30. He was born in 1831 at Greenfield, N. H., and received his preparatory education at Philips Andover College. He graduated from Harvard in 1857 and from the medical department of the University of Pennsylvania in 1859. After that he was a member of the faculty of the Philadelphia Polytechnic College and served as a surgeon in the Union army from 1862 until the close of the war. In 1867 he was elected Professor of Anatomy, Physiology, and Hygiene, and later of Biology, at the Central High School, where he taught continuously until compelled recently to retire on account of ill-health. In 1891 he accompanied Commander Robert E. Peary on his expedition to the Arctic regions.

Dr. Edgar L. Phillips died at his home in Goshen, N. Y. He was born at Phillipsburg in 1827. In 1858 he joined the gold rush to Pike's Peak, traveling overland with an outfit of drugs and medicines, and driving a big herd of cattle from the Missouri River to Pike's Peak. At the outbreak of the Civil War he became the surgeon of an Illinois regiment.

Dr. A. C. Andrews of Vineland, N. J., died on August 31 at the age of ninety-three years. He was born in Bethany, Conn. He was very prominent among those who labored for the success of Vineland, and was one of the founders of Holly Beach. Dr. Andrews' mother died at the age of ninety-nine years, and he was one of twelve children, one of whom is alive at the age of eighty years, and none died under seventy.

Dr. Edward Harris Johnson of Troy, Ala., was run over by a railway train and killed on August 27. He was a graduate of the Washington University Medical School, St. Louis, in the class of 1869.

Dr. W. Reid Thompson of Mackville, Ky., died on August 29. He was graduated from the Kentucky University Medical School, Louisville, in 1905.

Dr. L. P. Barclay, formerly representing Bausch & Lomb Optical Co., died on September 1 at the Loomis Sanatorium, Liberty, N. Y.

Dr. Staats Van Duzen Clark of New Brunswick, N. J., died in that city of locomotor ataxia after two years' illness. He was 60 years of age, and was formerly city physician, and also formerly a Freeholder. He was graduated from the New York College of Physicians and Surgeons in 1870. He is survived by his wife and two sons.

Dr. Frederick T. Rustin of Omaha, Neb., was shot and killed by an unknown assailant as he was entering his home on September 2. He was a graduate of the New York University Medical School in 1897, and served an interneship in the Presbyterian Hospital in this city.

Dr. John D. Holt of Berlin, N. H., died August 20, at his home in that city, after a long illness. He was born in Rumford, Me., in 1847, and was graduated from the Bowdoin Medical School in 1878.

Dr. Henry A. Tobey of Toledo, Ohio, died in Canada on August 21, at the age of 56. He was a graduate of the Miami Medical College, Cincinnati, in the class of 1875, and was for a number of years superintendent of the Toledo State Hospital for the Insane.

Dr. Edgar L. Phillips of Goshen, N. Y., died on August 30, at the age of 81 years. He was born in Phillipsburg, Orange County, N. Y., and was graduated in medicine from the Cleveland, Ohio, Medical College in 1851. He practised for a time in Ohio, then went to California for three years. During the Civil War he served as surgeon in an Illinois regiment. After the war he practised for a number of years in Galesbury, Ill., and upon his retirement removed to Goshen where he resided up to the time of his death. He was one of the early members of the Military Tract Medical Society, and was also a prominent Mason. He is survived by his widow, two sons, and two daughters.

Correspondence.

SOME REMARKS ON ATONIA GASTRICA.

To the Editor of the Medical Record:

Sir:—Statistics have shown that diseases among the present generation are on the increase although the mortality figure has come down somewhat, that is, the average duration of life of man is longer. Czerny has pointed out some causes, as for instance overtaxation of all the mental and bodily forces which is required to meet the greater demands of life, and wasting of these forces early in life without sufficient pauses for recuperation. He enumerates further the enormous proportion of increasing city population to which may be due the fact that the young of our generation are of less resisting power, the limited sojourn in free nature being unfavorable to the development of bodily strength. The better understanding of taking care of sick children may be the reason why numerous weaklings are kept alive who formerly would have succumbed and accounts also for increase of morbidity and decrease of mortality. The main cause of the weakness of the present generation is to be found, according to Czerny, in the prevailing disability or disinclination ot mothers to nurse their children; this fact explains the existing lack of resistance and greater inclination to diseases, especially of the intestinal tract. The administration of amylaceous substitutes makes much greater demands on the infantile intestinal tract than the natural mother's milk. Adynamy acquired through unsuitable nutrition during early childhood, be it in animals or in man, is never sufficiently compensated for in later life, however

generous the diet and care may be. From this lack of resistance in infancy, pointed out by Czerny, dates the inclination to atonia gastrica, that is, the relaxation of the abdominal muscles, the ptosis of the viscera, namely the stomach, the liver, the spleen, the kidney, the intestine, and also deviations of the uterus. There can be no doubt that the prevalence of perityphlitis may be explained by the prevalence of atonia gastrica in consequence of intestinal displacement acquired through improper nutrition during infancy. These many years I have called attention to the significance of abdominal relaxation, atonia gastrica, gastroptosia, splanchnoptosia, enteroptosia—all these are synonyms—in its relation to gastroenteritis, to neurasthenia, to chololithiasis, enteric and uterine hemorrhages, and to diarrhea, and I have demonstrated that the abdominal plaster belt, suggested by me, is the most effective of all the means known in the treatment of atonia gastrica provided the belt is of the best material and is skilfully applied.

On the occasion of the Congress on Tuberculosis I wish to emphasize that the treatment of atonia gastrica by means of the adhesive plaster belt is one of the most important therapeutic measures in cases of tuberculosis. By this method consumptives suffering, as most of them do, from abdominal relaxation, will be relieved from reflex cough and reflex vomiting and their circulation, nutrition, metabolism, and general condition will be decidedly benefited.

A. Rose, M.D.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PLAGUE—THE ANTIVERMIN CRUSADE—NURSES FOR THE TERRITORIALS—HOSPITAL WORK—AMBIDEXTERITY—HONORARY FELLOWS R.C.S.—POLLUTED MUSSELS—MORTALITY OF LAST QUARTER—OBITUARY.

London, August 21, 1908.

The outbreak of plague in the Gold Coast Colony, which lasted from the beginning of January until May, was met with commendable enterprise. Of the cases admitted to the hospital at Acera 50 per cent. recovered. Professor W. J. R. Simpson was engaged to investigate and advise, his previous experience as Medical Officer of Health for Calcutta and as Government Commissioner to inquire into the disease in Hong Kong pointing him out as well qualified for the work. His report has been issued in the *Gazette* of the colony, and shows the measures adopted. To suppress the disease in Acera itself they were: (1) Removal of the sick to hospital; (2) establishment of isolation camps; (3) fumigation of infected dwellings and in some cases their destruction; (4) destruction of rats, as there was an epizootic of plague among them; (5) inoculation with Haffkine's prophylactic. This last was the most popular measure, and over 15,000 of the inhabitants were inoculated. The eagerness of the natives to submit to this prophylactic was such that they struggled and even fought to be the first for the treatment. Professor Simpson is inclined to think that the inoculation did more than anything to save the situation, especially as the sanitary state of Acera was exceptionally bad. Outside the city the natives were equally eager to submit to the treatment, so that altogether over 31,000 persons in the colony were inoculated.

The measures adopted to prevent the spread of plague beyond Acera were: (1) The establishment round the town of a land cordon through which no native was permitted to pass without a passport, verified by a thumb mark and showing that inoculation had been undergone a week previously; (2) inoculation of all those leaving by sea and fumigation of their clothing, etc.; (3) inspection of all cargo and fumigation of all coverings. The infection of some localities emphasizes the value of these precautions, everything going to show that the land cordon and passports were most effectual. After the system was in force there was no instance of a sick person infecting villages beyond the cordon, as had previously occurred. The regulations raised no serious opposition, and nearly 4,000 passports were issued. As to sea passages, there was objection by the captains of vessels to receive passengers and sometimes even cargo. Professor Simpson thinks much of the inconvenience to trade was due to captains having their own notions. Considering that there are no ports and harbors, but the ships remain a mile or two from the shore, he does not believe infection is carried to them by the surf boats. Indeed, he says that with regulations such as those enforced at Acera there is no danger of infection by passengers, by cargo, or by rats. One cannot, however, be surprised that many captains were rather mistrustful.

To prevent future outbreaks a special staff has been appointed for cleansing and fumigating houses and destroying rats. Further arrangements have been made for the regular examination of rats so as to detect the first sign of plague among them.

The defect in the registration of deaths is pointed out as calling for removal since medical officers need the data about mortality to enable them to learn the existence of infective disease in the colony as soon as it appears in order to cope with it at once.

Naturalists as well as bacteriologists are in favor of the war on vermin. The society for their destruction, which is now only "incorporated," has among its supporters such authorities as the Duke of Bedford, the Earl of Dalkeith, Lord Ansbury and other eminent naturalists, as well as, of course, a long list of distinguished doctors. Rats claim the first attention of the new organization, but mice, mosquitos, sparrows, house flies and in fact all pestiferous insects and parasites will be included in its operations. It is hoped the war on these pests will be vigorously waged in other countries also. In Denmark there is an association for the extermination of rats which has been instrumental in passing an act enabling a small rate to be levied for the furtherance of its objects. Here we have to depend on voluntary work and the new "incorporated society" may serve to advise and reinforce the spasmodic efforts made by the many rural and district clubs scattered over the country which deal with the rat and the sparrow. No doubt the house fly, which is so annoying in the summer here, often carries the germs of typhoid and other diseases and is especially responsible for the many deaths of children from summer diarrhea. In Colombo at this moment we hear that enteric is raging and that its dissemination is due to the myriads of flies swarming in heaps of refuse which, in spite of all efforts, abound in the native quarters.

As supplementary to the arrangements for the medical service of the Territorial force, which I have previously described, I may add a note on the provision of nurses proposed by the Director General. It is too soon to say to what extent volunteers will come forward and Surgeon General Keogh does not anticipate any lack of patriotic response to the call. A matron will be required to join the administrative staff of each general hospital and control an establishment of thirty sisters and eighty-eight nurses. Every two years she will be given the opportunity of studying for one week the administrative duties of matrons in large military hospitals. These ninety-one nurses required for each hospital in time of war will be enrolled by local committees at each of the twenty-three hospital centers which county associations will take part in establishing.

As regards voluntary aid societies, the British Red Cross Society has already organized itself on a plan corresponding somewhat to that of county associations so as to focus county efforts. Last year the War Minister held a conference with the committee of the society; as a result of that meeting the army council after full deliberation has approved the proposals made by the Director General of the Army and Medical Service, Surgeon General Alfred Keogh.

Some statistics have been published as to the work of the hospitals and charities assisted by the Sunday Fund. It appears that the total number of beds in thirty-four general hospitals was 6,126; the average number occupied daily was 5,106. The total number of in-patients in the year 75,417; attendances of out-patients 3,236,499. The payments by patients amounted to £16,829; income, £706,757 (the average of three years); expenditure, £723,200 for the same period, but including investments of legacies—an item one would think should be afforded a separate entry.

At the London Hospital there are now 922 beds and the average daily number occupied was 792. In-patients numbered 13,532, out-patients' attendances 570,375. Payments by patients £2,202. Gross annual income and expenditure £94,469 and £127,328, respectively (three years' average). Approximate cost of an in-patient £1 18s 2½d per week, of an out-patient 8½d per head.

Sir J. Crichton-Browne, in an address at Cambridge, denounced as faddism the attempts of some people to urge the cultivation of ambidexterity. He said it was flying in the face of evolution, and there was no instance of any tribe which had grown out of it finding salvation in a return to it. The Japanese Ambassador had assured him that there was no truth in the statement of a lately published book that his countrymen were by law or practice ambidexterous. Left-handedness and ambidexterity, Sir James averred, was common only among idiots, and thought it might be of use in some special employments, on a large scale it tended to confusion and if pushed as far as its ardent advocates were clamoring for it, would necessitate the enlargement of our overcrowded lunatic asylums. You will perhaps remark on this that Sir James

displays as usual very positive opinions. I asked an eminent surgeon what he thought of the recent disputation on the subject, and he answered that he rather preferred "one right hand to two left ones."

On Tuesday Dr. Lucas Championniere went to the Royal College of Surgeons and signed the Roll of Honorary Fellows. This order of Fellows dates from 1900, and was instituted to celebrate the centenary. The King, the late Marquis of Salisbury, Earl Roberts, the Earl of Rosebery and of course many distinguished surgeons have been placed on the Roll.

Dr. Duchan, Assistant M. O. H. for Birmingham, has prepared a report on the consumption of mussels in reference to typhoid. In 62 out of 74 cases of typhoid noticed in four years, the onset occurred in the height of the mussel season. Twenty-five samples of raw mussels from fifteen markets were examined and many of them gave evidence that they had been exposed to pollution.

The registration returns show that during the second quarter of the year the death-rate for England and Wales was 13.8 annually per 1,000 persons living. This shows a fall of 1.8 per 1,000 below the mean rate in the ten preceding second quarters. It is, moreover, the lowest death-rate recorded in any second quarter since civil registration was established.

Harold L. Barnard, F.R.C.S., M.S. (Lond.), died on the 13th inst., at the age of 40. He had attained the position of Surgeon to the London Hospital, and had been teacher of anatomy and of physiology in the hospital college, as well as surgical tutor and surgical registrar. He had also been on the staff of the Metropolitan Hospital. He took his M.B. and B.S. with first-class honors in 1895, and the F.R.C.S. the same year, and the next proceeded to M.S. His health had been indifferent for some time, but he was able to get through much anxious work. He was recognized by his colleagues as a most skillful surgeon and original investigator. He wrote the article in Allbutt's System on Intestinal Obstruction and various contributions to the journals, particularly on abdominal surgery.

Sir Charles Gage Brown, K.C.M.G., M.D., LL.D., died on the 13th inst., aged 82. He was son of the late Commander Charles Brown, R.N., was physician and medical adviser to the Colonial Office and to the Crown Agents for the Colonies from 1874 to 1897, and latterly to some departments of the Foreign Office and the Audit office. He was made K.C.M.G. in 1897. He qualified in 1847, took M.D., St. And., in 1851 was elected F.R.C.P. (Edin.), 1870, and was President of the St. Andrew Graduates' Association from 1874 to 1897.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

CHOLERA—SEGREGATION OF LEPERS—A NEW MATERNITY HOSPITAL—SANITATION OF THE IWAHIG PENAL COLONY—PERSONAL.

MANILA, P. I., July 18, 1908.

THE present outbreak of cholera in the Philippine Islands is still giving cause for considerable alarm. While the number of cases has decreased in the province of Capiz and no further spread in the island of Panay has taken place, yet in the province of Pangasinan it does not show much evidence of coming under control. The disease has been spreading steadily and now involves the provinces of Tarlac, Nueva Ecija, Union, and Ilocos Norte, and so far the measures which have been taken to check this spread have not been rewarded with any great success. An average of about 200 cases per day is occurring now in the provinces mentioned above. Among these the mortality is reported as being about 50 per cent.

The plan of allowing the different municipalities to combat the cholera themselves has not proven very satisfactory from the standpoint of immediate results, and the present cholera outbreak is fairly conclusive evidence that the provincial districts are not yet ready for that share of local autonomy for which they have been constantly clamoring. At the time the more experienced cholera force of the Insular Bureau of Health was sent into the field, the disease had already assumed such proportions that it could scarcely be expected that it could be brought promptly under control. The municipal experiment was much of the same nature as if a house were set on fire in order to ascertain whether an untried volunteer fire company could put it out, and after it had failed, and the flames were becoming uncontrollable, then to call upon the regular fire department to battle with the situation.

In addition to the cholera previously reported, the disease has also made its appearance in ports of the province of Misamis, on the island of Mindanao; an average of about thirty cases per day is being reported. There are two towns so far reported as being infected, Balingasan and Cagayan. From the first appearance of the disease in that province up to the present time there have been 378 cases and 119 deaths reported. In spite of the fact, however, that the conditions in Pangasinan are not as encouraging as they might be, yet they are better than in 1902. The strenuous measures which were adopted at that time did much to arouse passive resistance in the people of the provinces, and the opposition which was engendered is still felt, and, no doubt, is largely responsible for the opposition which is made to sanitary measures. In many of the towns which the officials visit for the purpose of combating cholera, they find the people in fear and trembling lest their houses are to be burned down; but when they learn that such radical measures are not to be taken, and that the health authorities are really working for the material benefit of the inhabitants, in many instances their cooperation and help are secured.

In the report of the Bureau of Health for the quarter ended June 30, 1908, it is stated: "It is believed that sanitarians of experience will all agree that the best hope of completely eradicating the disease from the islands lies in the education of the masses with regard to the manner in which the disease spreads and the introduction of good water supplies. Both of these conditions are being met as rapidly as possible; the press, the schools, the churches, and the Government officials are all aiding in this work, and with the appropriation of $150,000 made by the Legislature, artesian wells are being bored as rapidly as the facilities of the Government will permit." Doubtless at a no very distant future the disease will be entirely suppressed, or at least be entirely under control by the sanitary authorities.

The work of segregating the lepers of the Philippines is still being steadily carried on. It is estimated that there are from twelve to fifteen hundred yet to be transferred to Culion. Less than two years ago there were more than three thousand five hundred at large in the islands. At the present time the provinces of Mindoro, Basbate, Romblon, Capiz, Iloilo, Antique, Oriental and Occidental Negros, Samar, and Leyte have been gone over a number of times, and, with the exception of a few isolated cases, it is believed that these districts are now free from lepers. The provinces of Cebu, Bohol, Ambos Camarines, Batangas, Tayabas, Albay, Sorsogon, Benguet, Lepanto-Bontoc, and Ilocos Sur have been gone over once, but experience shows that even with the best of care a considerable number remain after the first collection is made, and it is therefore expected that these provinces will be gone over several times more before the work can be considered as completed.

Another charity hospital has lately been added to the number which are gradually being established in the city of Manila. The present hospital is a maternity hospital and is located on Calle Quesada, in the district of Tondo, in a section which is well known for its poverty and ignorance. The building was donated by Mr. D. S. B. Johnston, of St. Paul, Minn., and the land, furnishings, and equipment were supplied by the Foreign Mission Society of the Methodist Episcopal Church, under the auspices of which the new hospital is being conducted. The institution, when completed, will have a capacity of upward of twenty beds.

The sanitation of the Iwahig Penal Colony, which colony, it may be remarked, had to be abandoned entirely by the Spanish Government on account of pernicious malarial fever which was encountered there, and which was responsible for the death rate of 200 per 1,000 per annum among the inmates of the institution at the beginning of the American administration, is still being successfully carried out. During the past year the death rate has been less than 10 per 1,000 per annum. The average number of persons confined to the hospital daily is about ten, and the total number of prisoners is about 500, so that it may be seen that the morbidity is very small and will compare most favorably with that in any similar penal institution in the United States.

Major William Stevenson, the senior surgeon at Fort McKinley, and Major William C. Borden, the surgeon in charge of the Division Hospital, Manila, both of the Medical Corps of the United States Army, have been directed to proceed to Washington for examination for promotion, and will leave the Philippines on the transport which is due to sail from Manila, August 15, 1908.

Progress of Medical Science.

Boston Medical and Surgical Journal, August 27, 1908.

Gastromyxorrhea.—Julius Friedenwald says that Kuttner considers the evidence of more than 5 c.c. of mucus in the fasting stomach as abnormal and when over 25 c.c. in amount as indicative of the condition which he terms gastromyxorrhea. Intermittent gastromyxorrhea occurs but rarely; the chronic or continuous form is more frequent. Kuttner was unable to find any evidence of locomtor ataxia in the cases of intermittent gastromyxorrhea that he investigated, though the sudden onset of the attacks as well as the sudden disappearance reminds one very much of a gastric crisis. The attacks may begin with prodromal symptoms, headache, loss of appetite, nausea, etc., and more usually begins in the midst of perfect health, often early in the morning soon after awakening. The most striking symptom of this paroxysmal attack is severe vomiting of large quantities of tough, slimy liquid, then of bile and intestinal juices, but it contains no food remains. During the attack the stomach refuses to retain food, drink, or medicine. The abdomen is retracted, the pulse small, the tongue dry, and the quantity of urine is much diminished. The attack may last from one to even twelve days, and ceases suddenly. In the beginning of an attack Kuttner advises a thorough lavage of the stomach, which he believes may terminate the attack. Morphine often gives temporary relief, and in cases of extreme exhaustion and weakness, normal salt solution enemata or infusions may be indicated. A careful investigation should be made as to the primary disorder, which, if possible, should be relieved. Chronic or continuous gastromyxorrhea may be associated with hypersecretion of acid or with various organic diseases, or may exist as an independent functional neurosis. The condition seems to be favored by the ingestion of starchy food. There are no characteristic symptoms. The diagnosis is established by the discovery of large quantities of mucus in the fasting stomach. Lavage should be practised for the removal of the mucus, provided there are no contraindications. Instead of this, Kuttner advises the administration of mineral waters.

Renal Insufficiency; the Importance of Its Early Recognition.—G. M. Randall suggests a definition for renal insufficiency as a criterion by which we may recognize certain constitutional diseases and disturbances of other organs and functions which tend to progress to organic renal lesions, chiefly spoken of as parenchymatous and interstitial nephritis. An interstitial nephritis cannot exist without involving the parenchyma. He considers the prophylactic treatment of the various forms of nephritis. The most conspicuous means of hereditary transmission are through syphilis and diabetes. The only effective line of defense is the everyday life. The daily diet is the greatest evil. The nitrogenous intake is generally far in excess of all demands, and it is beyond the physiological power of the kidney to eliminate the products of this excess without harm. There is no one more potent factor in the causation of diseases of the kidneys than an excess of the uric acid in the blood. A diet containing all necessary food principles may be selected that entirely eliminates the flesh of animals. Likewise, other common articles of diet which are rich in purin bodies may be dispensed with. Alcoholic beverages have no place in the dietary of the person desiring to live an efficient life.

New York Medical Journal, August 29, 1908.

The Treatment of Tuberculosis by the Administration of Mercury.—Barton Lisle Wright, U. S. N., says that six months ago they began the deep muscular injections of mercury in cases of tuberculosis, during which time two reports have been published. In the latter report appeared the results of forty cases then under treatment, showing 70 per cent. of improvements. Since this report appeared the percentage of improvements among these forty cases has risen to 85. They now had sixty-five patients taking the treatment, and from present indications the percentage of improvements will equal, if not surpass, that obtained from the forty already reported. Of the forty-one patients not taking the treatment but a few are improving.

An Experimental Study of the Trypsin Treatment in Cancer.—J. W. Weinstein, in order to test the efficacy of trypsin treatment in cancer, experimented in ten cases, and concludes that the trypsin cure is a total failure in his hands, even after a series of careful trials and painstaking labors, and, in his opinion, this new cure should be relegated to the vast legion of other so-called cures for cancer that have preceded it, and that the cancer problem so far remains unsolved.

Properly Constructed Filtering Beds.—Paul F. Bussman believes that instead of placing conducting pipes having broken joints on the bottom of a reservoir, they place them on the bottom of the river, lake, or whatever may be the source of the water supply, and cover them with successive layers of broken stone of large size, and then stone of a smaller size, upon this gravel, followed by coarse sand. Then all the pure water will pass to an unlimited amount and the foreign matter held in suspension will not be deposited on the filter, provided the flow through the filtering bed is not greater than the flow over the same. Foreign matter held in suspension in a liquid will follow the lines of least resistance. If for every million gallons of water used in a day a filtering bed of one acre in size was used, the flow through the filter would be at the rate of one yard a day. A body of water flowing at the rate of one mile a day would be a very slow natural current; still the flow would be one thousand seven hundred times faster over the filtering bed than through the same, and where this is the case there will be no deposit of foreign matter to clog the filter.

Observations on Open Air Treatment.—John Carling says that, admitting that a maximum amount of pure air to the lungs is the main consideration in the treatment of bone tuberculosis as well as pulmonary, it follows that dry inland air, which encourages deep breathing, is to be preferred to the humid atmosphere of the seashore. Another important advantage is the matter of shade. His own experience in the tropics, where the sunlight is intense, and his further observations on the effect of strong sunlight upon patients undergoing open air treatment, convince him that it is decidedly harmful. The firm nature of the soil is another reason for preferring the country to the seashore in bone tuberculosis. The yielding nature of the seashore makes locomotion difficult for children wearing apparatus, and is a constant strain on the weakened and diseased joints. For rickets and cases of general malnutrition, where there is no actual disability, and sea bathing can be indulged in, a residence at the seashore may be beneficial. But for bone and joint tuberculosis a dry inland climate is to be preferred. Patients undergoing open-air treatment do much better in winter than in summer. This may be due to (1) the diminished amount of strong sunlight; (2) the cold air, which contains more oxygen than the warmer and more rarified air of summer; (3) the stimulating effect of the cold on the functions of respiration, resulting in deeper and more frequent breathing, and consequently a greater supply of oxygen to the tissues. He says that in spite of the success met with in treating all classes of diseases with an abundance of pure air, the large city hospitals are doing practically nothing to give the patients the benefits of open-air treatment. Every large city hospital should have a country branch. With a well-equipped hospital car in charge of a member of the house staff, patients could be transferred from the city institutions to the country, not only without injury, but with comfort.

Journal of the American Medical Association, August 29, 1908.

Salt Metabolism and Diabetes.—E. P. Joslin and Harry W. Goodall have studied the question whether the withdrawal of salts from the diet might lead, as a rule, to the production of an acidosis in a healthy person or to the aggravation of such a condition already existing in a diabetic patient. The result of their experiments indicate that such is not the case. They have also investigated the occurrence of edema in diabetes, which is, they say, not infrequent in cases presenting marked acidosis and occurs coincidently with restrictions of the carbohydrates. These patients were given sodium bicarbonate, but the authors do not recognize this latter as a factor and they have never seen it cause edema in a mild case of diabetes. They consider the edema as probably due to the increased production of acids causing injury to the kidneys, thereby leading to retention of salt (not salts). This view appears to be supported by the history of some of their patients in whom the ingestion and excretion of chlorin was observed. Patients in diabetic coma rarely, if ever, show signs of edema, and show diminished chlorin in the urine if alkalies are given. If the withdrawal of salt from the diet in a severe case of diabetes prevents the occurrence of edema, as was observed, the administration of salt should lead to salt retention and gain in weight. This was found to occur. In patients with deficient chlorin in the body, edema is not likely to occur, but they are more prone to coma because of the greater concentration of the acids in the system. The authors, therefore, advise the careful administration of salt along with sodium bicarbonate in the prophylactic and actual treatment of diabetic coma.

Obstetrical and Surgical Toxemias.—H. G. Wetherill concludes from his study and observation that: 1. Toxemias of pregnancy, sepsis, sapremia, late chloroform

poisoning, etc., may have many characteristics in common, and from the clinician's standpoint may be grouped together for purposes of study, prevention, and treatment. 2. Chloroform may cause such toxemia and liver lesion *de novo*. 3 It also aggravates toxemias already existing of the hepatic type. 4. Pregnancy, retained blood, and clots of concealed hemorrhage, the sapremia from decomposing placental and fetal debris, sepsis, and the autointoxication of overfeeding and drinking and of coprastasis predispose patients to such liver lesions. 5. Urinary insufficiency with acidosis and a high ammonia coefficient, retinal hemorrhages and neuroretinitis, regurgitant vomiting of the mucous, grumous, and bilious type, with or without slight jaundice, and with or without albuminuria, constitute the syndrome of such toxemias. 6. Albuminuria, when it occurs, may be, and often is, late in developing and should be regarded as secondary rather than primary—as a result, not a cause of the condition. 7. In such toxemias of pregnancy with or without pernicious vomiting, the uterus should be promptly emptied, but without the use of chloroform and, if possible, without any other anesthetic. 8. Fasting and forced elimination by the skin, kidneys, and bowels offer the best prosepects of cure after, as well as before, the removal of the cause.

New Sign of Malingering.—C. F. Hoover describes a test of malingering which he has used in fever cases with good results. It is applicable in case of feigned paralysis of the lower limbs and consists in watching for the counteraction of the opposite leg when an attempt is made to raise one leg by the subject when in a dorsal position. In the normal individual there is always an opposite action in the unused leg unless it is inhibited, and in case of hemiplegia it appears whether there is any muscular action in the paralyzed limb or not. In two cases in which paresis of one leg was claimed to exist, when the patient was asked to lift his well leg off the couch, the other was pressed strongly against the surface when resistance was offered to his raising it. When, however, he was requested to lift the alleged paretic leg no downward pressure was observed in the other. The absolute lack of complemental resistance in the normal leg was also observed in a case of hysterical hemiplegia and in a case of hysterical paraparesis inferior, with abasia, in which the patient could bow himself into opisthotonos, this sign was observed. The sign appears to Hoover to be of special value as depending on the exhibition of a function from the normal leg which must always be present if the patient does not inhibit the impulses to the lower extremities.

Venesection.—J. Daland remarks on the present neglect of the therapeutic use of venesection, which he attributes to the prejudice caused by its former overuse, the fear of weakening already enfeebled persons, the prejudice on the part of the laity, the failure of many physicians to recognize its indications and limitations and, lastly, to the belief that a small weak pulse is an absolute contraindication to blood-letting. Usually it is resorted to as a palliative or life-saving measure, but he points out that it is indicated in certain cases of valvular disease with well-marked failure of compensation, in which there is extreme orthopnea, cyanosis, tumultuous cardiac action, small rapid pulse, distention of veins of head and neck, weak apex beat displaced to the left and seen and felt over a larger area than normal; increase in area of cardiac dullness to the left and right, and not infrequently accentuation of the pulmonic second sound. Blood-letting is especially indicated if these symptoms and signs are progressive in spite of the ordinary cardiovascular remedies. In such cases twenty ounces of blood may be taken slowly from the median cephalic vein, and if myocardial degeneration is not excessive the relief is prompt. Here the small weak pulse is due to venous congestion and overdistention of the right side of the heart. The relief may be only temporary, but it gives ordinary remedies a chance to act which was before impossible. The above symptoms may occur late in the disease affecting the mitral and aortic valves. In well-marked myocardial degeneration, bleeding is useless. Venesection is of great value in mitral stenosis with extreme right ventricular dilatation with failure of compensation and also frequently in such failure of compensation as described occurring in the course of arteriosclerosis. It may also be useful in acute pulmonary edema from right heart dilatation, and in aneurysm of the arch of the aorta the abstraction of eight or nine ounces can temporarily relieve dyspnea or pain. In all cases of failure of compensation of the kind described, exudates in any of the serous cavities should be removed before resorting to venesection. Lastly, Daland speaks of blood-letting in case of extremely dilated right heart from pulmonary obstruction in pneumonia, in which the abstraction of from 20 to 24 ounces may save life. Certain deaths following venesection in pneumonia are due to a prior formed thrombus, others to previous myocardial disease. The bleeding should, therefore, be not too long delayed to prevent thrombosis or excessive toxemia. The good results of bleeding in uremic hypertension and in certain cases of apoplexy are also mentioned.

Nasal Analgesia.—Dunbar Roy calls attention to the symptom of nasal analgesia, understanding by this term an insensitiveness of the nasal mucosa, making it possible to perform all kinds of instrumental manipulations in these cavities without discomfort to the patient or the use of any local anesthetic. He finds no mention of it in the literature and apparently it has not been considered by the majority of surgeons, judging by the replies received from a number of them. Roy is convinced that the present teachings are largely wrong as regards the cause of the progressive deafness that comes on insidiously in young adults and those of advancing age who have previously shown no symptoms of nose or throat derangement, and he thinks that this symptom of nasal analgesia may prove a valuable point in the future management of the conditions. He is convinced that this form of progressive deafness is a disease *sui generis* and that the aural and nasal musoca undergo the same pathological changes. The more advanced these changes the less favorable the prospect of the improvement of hearing. The same changes finally occur also in the auditory nerve. He thinks lack of sensibility in the nasal cavities in these cases has a bad prognostic significance. The symptom, he thinks, may aid us in directing the treatment to measures that will increase the vitality of the nasal and aural tissues and their nerve supply. Hence the value of potassium iodide in these cases.

The Lancet, August 22, 1908.

The Alleged Discovery of Syphilis in Prehistoric Egyptians.—G. Elliot Smith takes issue with the statements of Professor Lortet and Dr. Fouquet that certain lesions found in the bones of prehistoric Egyptians are due to syphilis. He points out that "ulcers" presenting the closest resemblance to those described by these men are of very frequent occurrence in Egyptian bones of every age when they are actually buried in contact with the soil. Bodies buried in rock-cut tombs or in coffins are exempt from such injuries. When such mutilated bones are removed from the soil the burrows of small animals can be seen leading to the "ulcer." Fragments from the walls of these burrows, and also those taken from the damaged surfaces of bones, were found to contain fragments of the elytra of beetles. He does not think there is any doubt but that the injuries described by Professor Lortet and Dr. Fouquet as the result of syphilis were produced really long after death and burial and that the damage was done by small beetles. They were bound to admit that, so far as they knew at present, syphilis did not occur in Egypt before the time when intimate communication with Europe was established.

Generalized Edema of the Fetus.—W. W. Kling reports two cases of generalized edema of the fetus, a condition which has frequently been observed both in man and in animals. The main conclusions to be drawn appear to be that edematous children are usually born of women of about the ages of 30 to 35 years who have had previous abortions or premature stillbirths. The mother's health is rarely good, but there is no specific disease associated with the condition. Evidences of syphilis have only been found in a few instances. The labor is usually premature but the large size of the child often causes obstruction during labor and the friability of the tissues when present renders artificial aid difficult. While the maternal prognosis is good the children are either stillborn or only live a few hours. Subsequent pregnancies may end either normally or with premature stillbirths or, in a few cases, with more edematous children. The causation of this condition is very obscure.

A Case of Congenital Hypertrophic Stenosis of the Pylorus Treated Medically.—Norton B. Clowes reports the case of a baby weighing eleven pounds at birth in whom artificial feeding was begun on the second day. The child failed to gain in weight and various foods were tried. Finally on deep palpation an indurated pylorus could be felt, about the size of the end of the thumb. It was situated one inch above and to the right of the umbilicus. For over two months he continued to lose in weight and developed the typical expression,

hollow eyed, emaciated face, extreme transverse wrinkling of the forehead, etc. Each time the tube was passed into the stomach, even when not directly after a feeding, it contained from two to three ounces and sometimes more of food and slimy mucus. Five months after birth he had just gained two ounces over the birth weight, *i. e.* he then weighed eleven pounds and two ounces. He then gradually began to improve and soon weighed what a child of his age should weigh. He continued to improve and was soon looked upon as being a well child.

A Case of Ipecacuanha Poisoning.—Such a case is reported by R. T. Harrison because of its rarity as a (supposed) cause of death. The boy, a negro, was in the habit of stealing alcoholic mixtures from the dispensary and, by mistake, drank a considerable portion of vinum ipecacuanhæ. He apparently chose his drinks by smell. He had violent vomiting and retched considerably. The extremities were cold and clammy. The pulse was rapid. He complained of pain in the abdomen and had slight abdominal cramps. He was given large quantities of water and a little brandy. The first portion of the vomit had been thrown away before his arrival but he managed to secure about half an ounce from the bottom of the chamber. It showed nothing distinctive in smell or appearance. As his condition was not improving under such treatment as could be applied at the time and place, he hurried to the surgery to prepare for him. Five minutes later the messenger reported that he was much worse; he died one and a half hours after the first symptom. At the post mortem, fourteen hours after death, they found subacute congestion of the stomach and first two feet of the intestine. It was decided that an analysis of the stomach contents and vomit was unnecessary and a verdict was returned of death through misadventure.

Münchener medizinische Wochenschrift, August 18, 1908.

Motility of the Stomach.—Kaestle says that the examination with the .r-rays is the best means for studying the motility of the stomach as well as its position, form and size. He has made over two hundred observations on eighty persons with healthy stomachs using various bismuth salts in the technique of the procedure. The parts of the mixture first introduced remain for a short time in the upper pole of the stomach and then descend to the deepest part of the organ; the further additions do not cause the lower pole to descend. The ingesta begin to be emptied very soon after their entrance, peristaltic waves running across the organ and periodically shutting off the pyloric antrum. After about one hour's time the lower pole, which has remained stationary, rises to a considerable distance, and this moves the pylorus to the left and upward. This rising of the stomach allows the escape of the last remains of the food, the closing contraction of the organ driving it toward the exit. In two of the persons examined the stomach was empty in two hours; at the end of three hours this result was reached in the great majority of the subjects, especially in men; most of the women required three and one-half hours for attaining this result. The normal time required for emptying the stomach ranges, therefore, from two to three and a half hours. Two to three hours are taken up by the stay in the small intestine, while the motion of the shadow in colon is very slow and quite different for different individuals.

Serum Diagnosis of Syphilis.—Taege gives a detailed account of the Wassermann reaction for syphilis. Its purpose is to decide whether a general infection with the virus in question has already taken place or in other cases whether an old infection is still present. The reaction depends upon the presence in the organism of an antibody to the syphilitic toxin or antigen, which in this case is the *Spirochæta pallida* or its products. As this germ has not yet been grown in the laboratory the extract of an organ of a syphilitic fetus is used as the source of the antigen. The antibody is sought for in the blood of the patient, a complement being necessary to produce the binding of the antigen to the antibody. It is the using up of such complement present in every serum by the interaction between the two specific products of syphilis that is looked upon as the indication that such bodies are present in the serum examined. To demonstrate this disappearance of complement a hemolytic serum is obtained by gradually immunizing a rabbit to the red blood cells of a sheep; the serum of such a rabbit contains a hemolysin which is a compound substance consisting of the normal complement and of an amboceptor. The serum loses its hemolytic property on warming to 56°, for this temperature destroys the complement. The addition of the serum of a guinea pig brings back the hemolytic property, for such serum provides the necessary complement for the hemolysin. But if the red cells of the sheep are mixed with the hemolytic serum of a rabbit, the serum of a guinea-pig and, in addition, with the syphilitic antigen and the serum of a patient suffering from syphilis no hemolysis takes place, because the complement necessary for the hemolysin has been used to bind the syphilitic antigen with the antibody of the syphilitic serum. The inhibition of the hemolysis is accordingly the indication that a specific antibody exists in the blood of the patient examined and that, therefore, he is suffering from a syphilitic infection. The occurrence of hemolysis, on the other hand, speaks for the absence of such infection, the complement of a guinea-pig's serum being used to produce a hemolysin and not to effect the interaction between the antigen added to the mixture and an antibody, the latter being absent from the serum examined.

Paratyphoid Infection.—Bingel says that the infection of the organism with the paratyphoid bacilli may produce a clinical picture similar to that of typhoid fever. Quite frequently, however, the infection produces a different symptom-complex which has most in common with acute gastroenteritis. The paratyphoid infection is, therefore, not to be looked upon clinically as an irregular typhoid fever, but as a gastroenteritis differing from the usual types of that disease by the presence of a specific excitant. The name "paratyphoid fever" is quite misleading as far as the bedside picture of the disease is concerned, however applicable the word "paratyphoid" may be to the bacilli causing the disease.

Local Anesthesia in Operations for Hernia.—Nast-Kolb says that local anesthesia is used in the Heidelberg Surgical Clinic for almost all operations on hernia and is preferred to lumbar narcosis; only in the case of very anxious patients inhalation anesthesia is used as an auxiliary measure. Local anesthesia, however, is never used in children under 10 years. Both reducible and irreducible inguinal and femoral herniæ can be operated upon under such anesthesia, but in handling the intestines any unnecessary pulling upon the mesentery is to be avoided. Many adhesions between the sac and the contents are a contraindication to local anesthesia. In some cases morphine or scopolamine is administered one half hour before the operation. The sense of touch is retained by the patient while pain is deadened in the anesthetized portions of the tissues, and gentleness is called for in the technique of operating. Primary union of the wound has been the rule and no bad effect upon the postoperative course could be discovered, with the exception of marked pain that is felt for several hours after the operation. The few disadvantages of local anesthesia such as the necessity of waiting for the action of the narcotic and the changes produced in the anatomy of the parts by the infiltrating fluid are more than made up by the small degree of danger, by the absence of vomiting, the possibility of asking the patient to help the operator by coughing, straining, etc., the possibility of operating without an anesthetizer, and the absence of the necessity to watch the patient for some time after the operation which of course must be done in inhalation narcosis. The above data were gathered in the course of 92 operations for hernia performed in the period of seventeen months.

Deutsche medizinische Wochenschrift, August 13, 1908.

Time of Conception.—Schaefer had opportunity to examine four aborted fetuses and obtain full data as to the time of intercourse preceding the conceptions. He concludes that the views of Sigismund and Loewenhardt according to which the impregnated ovum belongs to the first missed mentsrual period are probably correct. Menstruation consists of the phenomena accompanying the abortion of the unimpregnated ovum. Ovulation and impregnation probably precede the date of the first missed menstrual period by a few days; rarely they may coincide with it. Spermatozoa are capable of remaining alive in the genital tract of the female during the whole period elapsing between two menstruations and thus preserve their impregnating function. A fruitful intercourse can take place at any time, but the postmenstrual period is most favorable for conception. Subjective symptoms of pregnancy may appear very soon after the impregnated ovum is embedded in the uterine mucosa. In reckoning the time of pregnancy, the type of menstruation, the beginning of the last menstruation and its character, the date of the last intercourse between the last menstrual period and the first missed period, and the appearance of subjective symptoms must be taken into consideration. In regular types of menstruation the probable time of impregnation may be obtained by the addition of the number of days intervening between menstruations minus three to the beginning of the last period.

Book Reviews.

Sprachstörungen und Sprachheilkunde. Beiträge zur Kenntnis der Physiologie, Pathologie, und Therapie der Sprache. Herausgegeben von Dr. Med. H. Gutzman, Privatdozent an der Universität Berlin. Mit 15 Abbildungen im Text und einem Porträt. Berlin: Verlag von S. Karger, 1908.

In the preparation of this manual of disturbances of speech and therapy therefor the editor has had the co-operation of some twenty-two colleagues in the European cities and of one American, Dr. G. Hudson Makuen, of Philadelphia, who writes on "The Speech of the Feeble Minded." The book is not a systematic text-book in the ordinary sense of the term, but rather a collection of essays by the various collaborators on topics suggested by the title. Most of these essays are short, and all of them are practical. Some have already appeared in the journals. Each author has been allowed to print in his own language. Consequently the chapters are variously in English, French, and German.

An Abridgement of Practical Medicine and Allied Sciences. Arranged in Alphabetical Order, with Definitions of Principal Medical Terms. By J. Candor McLaughlin, M.D., Kansas City, Mo.

The author of this tiny pocket volume announces that it is especially valuable to the physician who has to take a State Board medical examination, as by reading this one book he will have no need to obtain and read other numerous and larger volumes. In the face of this announcement we find it stated that the external carotid artery supplies the anterior part of the brain, eye, forehead, and nose; the branches of this artery are also incorrectly given. The author's bacteriology is no better than his anatomy, as witness the following: "*Bacteria-Malaria*—Bacillus, aerobic, rods in filaments with spores at each end." The chemistry is of about the same calibre, but we have no room for further illustrations.

Text-Book of Ophthalmology. By Dr. Ernst Fuchs, Professor of Ophthalmology in the University of Vienna. Authorized Translation from the Eleventh Revised and Greatly Enlarged German Edition with Numerous Additions, by Alexander Duane, M.D., Surgeon Ophthalmic and Aural Institute, New York. Third Edition. Philadelphia and London: J. B. Lippincott Company, 1907.

The third edition of Fuchs' work, based on the eleventh German edition, greatly added to by the translator and editor, Dr. Duane, is now on the market. The text occupies 877 pages. The book is well printed and fully illustrated. The matter of primary importance is printed in larger, the matter of secondary importance in small, type.

The first forty-seven pages comprise Part I. They are devoted to the objective examination of the eye and to functional testing of the eye. The diseases of the eye are taken up in Part II. and considered in logical order. The anatomy of the individual parts is given at the beginning of each chapter. The consideration of clinical conditions is very comprehensive. The symptoms, pathological changes, and phenomena of every character are discussed in detail in a masterly manner, born of the exceptionally extensive experience and close, exact observation of the very able author. Illustrations and statements of writers other than the author are employed wherever they can be utilized to increase the sum total of the information given on any of the subjects discussed. There are no marked departures from the methods of classification employed in former editions. The operations peculiar to various parts of the eye are given consideration in the chapter devoted to each part, but a chapter on "Eye Operations in General" is found at the end of the book. Chapters on "Disturbance of Motility of the Eye" and "Anomalies of Refraction and Accommodation" follow those treating of diseases of the eye. The relation of diseases of the eye to general diseases is not given consideration in a separate chapter, but is briefly discussed in the chapters devoted to the different parts of the eye.

The treatise is one of the best in any language. It is of value, not only as a text-book, but as a book of reference and of guidance to all who have to do with the clinical problems of ophthalmology.

Hermaphroditismus beim Menschen. Von Franz von Neugebauer, Vorstand der Gynäkologischen Abteilung des Evangelischen Hospitals in Warschau. Leipzig: Verlag von Dr. Werner Klinkhardt, 1908.

The author devoted fifteen years to researches for this work of 748 large quarto pages. The 1,891 cases from literature and personal observation which he presents and carefully analyzes show that the time and study he devoted to the subject were well employed. Von Neugebauer modestly offers his enormous work as a mere handbook to aid such colleagues as may institute investigations regarding any of the questions in connection with hermaphrodism. While as a literary aid the book certainly fulfills the author's promises, it does far more. It enters deeply into genital embryology; it studies historical facts as to doubtful sex-determination; it investigates the legal and sociological questions that relate to or have arisen regarding such errors as may be due to lack of definite recognition of the sexual organs. In a most admirably condensed classification of the reported cases the author presents 109 divisions of his subject, enabling prompt reference to any of the circumstances in which differentiation of sex is required for literary, forensic, or sociological purposes. The author has shown marked ability in avoiding even the boundary lines of pornography, with which literature on sexual subjects abounds. He presents scientific facts as only a careful, conscientious scientist can. The fact that his list of quoted authors contains over 1,500 names gives an idea of the extent of his literary researches. The book is well illustrated.

Righthandedness and Lefthandedness, with Chapters Treating of the Writing Posture, the Rule of the Road, etc. By George M. Gould, M.D. Philadelphia and London: J. B. Lippincott Company, 1908.

In this collection of essays, previously published for the most part in the *Popular Science Monthly* and various medical journals, Dr. Gould deals in his usual interesting way with the causes and the consequences of righthandedness. The origin of righthandedness is referred to the dominance of the right eye in vision. The preference of the right hand in operations requiring special skill is shown to be due to the fact that such operations at first must be directed by the eye, and if the right eye is the stronger it must insist upon the more delicate movements being made by the hand under its direct guidance. Further, the development of sign language and of written language, the first chiefly and the second entirely carried out by means of the right hand, under the control of the dominant right eye, determined the location of the speech center in the left brain, and in consequence the acts performed in response to a command are naturally controlled by the brain centers nearest to the speech center. Even the apparent exceptions to this dependence of righthandedness upon righteyedness really prove the rule. In violin playing, for example, the more difficult fingering is done by the left hand, but this is because the right eye can guide the fingers of the learner better, for if the fingering was done with the right hand, the foreshortening occurring as the right eye glanced along the neck of the instrument would handicap one seriously. This is the theory briefly stated, but one must read the argument as developed by the author in order to follow it understandingly. It is the most satisfactory explanation of the dominance of the right hand that has ever been offered. Other essays are on the Rule of the Road, Two-handed Synchronous Writing, the Writing Posture, Righteyedness and Lefteyedness, all more or less related to the title subject. Dr. Gould is an original thinker and one who can express his thoughts in a forcible manner, and whether or not one agrees with him, his writings stimulate thought and furnish exercise for the mind. The volume under consideration offers no exception to the rule.

The Development of Ophthalmology in America, 1800 to 1870. A Contribution to Ophthalmologic History and Biography. An Address Delivered in Abstract for the Section of Ophthalmology of the American Medical Association, June 4, 1907. Revised and Enlarged. Illustrated by Selected Portraits and Cuts. By Alvin H. Hubbell, M.D., Ph.D., Professor of Clinical Ophthalmology in the University of Buffalo. Chicago: W. T. Keener & Company, 1908.

Hubbell's booklet is one of much interest to American ophthalmic surgeons, since it presents in one volume the historical facts in regard to the development of ophthalmology in America. The volume contains 197 pages. It is very entertainingly written and fully illustrated. There are portraits of twenty-eight distinguished ophthalmic surgeons, two of whom are now living, and, in addition, cuts of various ophthalmic hospital buildings that have passed out of existence. A short history of the founding of the various large eye and ear clinics in America is given; also a biographical sketch of many of the prominent surgeons who have served to advance this branch of medicine in America. The principal works on ophthalmology that appeared before 1870 are reviewed briefly and the advances in ophthalmology originating with Americans during that period are enumerated. The work should be in the library of every American ophthalmic surgeon.

Hospital Training-School Methods and the Head Nurse. By Charlotte A. Aikens, late Director of Sibley Memorial Hospital, Washington, D. C.; late Superintendent of Iowa Methodist Hospital, Des Moines, and of Columbia Hospital, Pittsburg; Associate Editor of the National Hospital Record. Philadelphia and London: W. B. Saunders Company, 1907.

This book differs from others on nursing in that it discusses the problems that have to be faced and solved by the various training schools for nurses, and also, in a lesser degree, by head nurses. The writer seems to draw her material from an extended experience and much observation, and she has some very decided opinions on many topics in connection with nursing. The book is original, breezy, and healthy. As a sample of the author's style, and also of the sanity of her views, we append an extract: "What possible good it can do for nurses to spend time in learning how to apply the flame test for sodium, potassium, calcium, strontium, by borax head and Bunsen burner, is a question too deep for the average mind to answer. What practical benefit can it be to the average patient or satisfaction to a doctor to have a nurse who knows the deep mysteries of sugar, and can make a comparison of sucrose, glucose, levulose, lactose, or who can explain their preparation, composition, properties, digestion, and food value? Just how much further probationers and pupil nurses will be asked to go in the study of chemistry, pharmacy, bacteriology, and pathology in the next ten years—where we may expect to stop in our attempt to teach nursing—is a matter for speculation. A good many people believe we have reached a time when it is necessary to draw the line and popularize the slogan 'Back to Nursing!'" Many of the lecturers in our training schools might read the first part of this book with considerable discomfort to themselves, and much subsequent benefit to the rest of mankind. "Back to Nursing!" is the aim of the book, and it has our entire approval.

Surgery. Its Principles and Practice. By Various Authors. Edited by William Williams Keen, M.D., LL.D., Emeritus Professor of the Principles of Surgery and Clinical Surgery, Jefferson Medical College, Philadelphia. Volume III. With 562 Text Illustrations and 10 Colored Plates. Philadelphia and London: W. B. Saunders Company, 1908.

The third volume of this system is devoted to an important and interesting series of topics. The opening chapter is an exceedingly fine treatise on the surgery of the head by Harvey Cushing, and covers over two hundred and fifty pages. The eminence of its author in this field lends unusual authority to the very detailed discussion he gives of the diagnostic and operative measures concerned, and the illustrations are worthy concommitants of the text. The operative technique of cranial surgery, which has been so much amplified of recent years, is amply described, and the operator will find here mention of many new devices and methods. The surgery of the neck is discussed by E. Wyllys Andrews, and here also there is much that is new in the way of technique, including Crile's method of temporary clamping of the carotoids and block dissection of the neck. The following chapter is by Albert Kocher on the diseases of the thyroid gland, and contains interesting material in the sections on the parathyroids. For the symptom complex known as Graves' disease he suggests the term thyrotoxicosis as a comprehensive appellation for the various types encountered. After referring to the various other therapeutic measures available for this disorder, he says of surgical treatment that, "To say that this is still the best is not enough. It has proved itself superior to any other form of treatment." The paragraphs on the technique of goiter operations are somewhat disappointingly brief; for example, while it is stated that general anesthesia should be avoided as much as possible, only three lines are given to the description of the application of local anesthetics. A valuable chapter on the nose and its accessory sinuses is contributed by Harmon Smith, and the two following ones on the larynx and trochea and the surgery of the thorax are by George E. Brewer. In the former of these Dr. Brewer describes and illustrates the procedure of bronchoscopy, and in the latter several new operative methods, including the application of Sauerbruch's pneumatic cabinet, are discussed. The chapter on the surgery of the breast by John M. T. Finney is fully worthy of the importance of this subject, the sections on the prognosis and treatment of carcinoma being especially admirable. The chapter on the surgery of the mouth, teeth, and jaws has been allotted to Edmund Owen, and that on the tongue to John C. Da Costa. The subject of abdominal surgery is broached by John C. Munro in three chapters on the technique of abdominal surgery, surgery of the abdominal wall, and surgery of the peritoneum, respectively. George Gottstein, of Breslau, is the author of a copiously illustrated chapter on the surgery of the esophagus, in which esophogoscopy is dealt with at great length. The volume closes with chapters on the surgery of the stomach by A. W. Mayo Robson, on the liver and bile passages by William J. Mayo and Charles H. Mayo, and on the pancreas and spleen by B. G. A. Moynihan.

Confessio Medici. By The Writer of "The Young People." New York: The Macmillan Company, 1908.

This is a volume that is at once both unpretending and charming. From the title-page, through the preface, the ten essays which the book contains, and right down to the last line of the epilogue the author in a most delightful way discourses on the philosophy of the physician's life. Ambrose Paré is really the subject of the essay on a "Good Example," and the author does well to rescue Paré from present day forgetfulness. Throughout the volume much sage advice is given to the young practitioner, and the shrewd observations of the author and the delightful language in which they are conveyed both make the book one which every educated reader will enjoy. There is a timely and somewhat incisive essay on psychology, and an interesting application of the three caskets of Portia to the physician's pursuit of practice. The book is, of course, written by a cultured man, for cultured readers, but yet we are reminded that culture has its limitations, and should be put in its proper perspective in the scheme of daily life and practice: "The proper field for culture seems to be among them who, not having much the matter with them, enjoy talking. But not all even of them enjoy listening. I know of one, who said to a friend, 'I don't want my doctor to talk to me about the National Gallery,' which is a shrewd saying, and has taught me to avoid all such dangerous topics. Anyhow, people who are seriously ill care no more for preciosity in us than for gold-dust in beef-tea. What they want is a man who has just had and cured a case exactly like theirs, and he need not be a judge of anything outside their insides. It is poor comfort to them to know that he is very fond of really good poetry." It is an open secret that Mr. Stephen Paget is the author of this charming book.

Diseases of the Breast. With Special Reference to Cancer. By William L. Rodman, M.D., LL.D., Professor of Surgery in the Medico-Chirurgical College of Philadelphia; Professor of Surgery in the Woman's Medical College of Pennsylvania; Surgeon to the Medico-Chirurgical Hospital, etc. With 69 Plates, of which 12 are printed in colors, and 42 other Illustrations. Philadelphia: P. Blakiston's Son & Co., 1908.

Tumors of the breast are so frequent and their early diagnosis and treatment are so important that the subject affords ample material for a special volume. The author's clinical experience has been wide enough to enable him to speak with authority, and the reader finds here a thoroughly satisfactory and modern discussion of this group of affections. All of the diseases of the breast are considered, including the inflammatory conditions, though, as is natural, over one-half of the volume is devoted to carcinoma. In the chapters on the various aspects of this disease the theories of etiology are discussed with thoroughness and judgment, the description of the symptomatology and diagnostic guides is complete and helpful, and the views on treatment are eminently sound. It is the author's belief that surgery should cure one-half of the cases if resorted to early in the disease, while his opinion of the value of radiotherapy and the other methods of treatment is not very high. A considerable number of well selected and executed illustrations contributes materially to the value of this most admirable work.

Applied Physiology. A Manual Showing Functions of the Various Organs in Disease. By Frederick A. Rhodes, M.D., Professor of Physiology and Embryology, Medical and Dental Departments of the Western University of Pennsylvania; late Physician-in-Charge to the Reineman Hospital and the Kaufman Clinic; formerly Assistant to the Chair of Clinical Medicine, West Penn Medical College, etc. Pittsburg, Pa.: Medical Press, 1907.

The subject of pathological physiology has received but scant attention at the hands of American writers, and the present is a praiseworthy attempt to fill in this gap. While the matter is treated very largely in a synoptical manner and the outlines furnished could well bear a little more filling in, the volume should prove a useful guide to students, and also be of value to more experienced readers desirous of reviewing the mode of causation of the symptoms of disease. The volume is in many ways so excellent that it is a pity the proofreading was not more carefully done.

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Thirtieth Annual Meeting, Held at Montreal May 11, 12, and 13, 1908.

(Special Report to the MEDICAL RECORD.)

DR. HERBERT S. BIRKETT OF MONTREAL, PRESIDENT.

Monday, May 11—First Day.

President's Address.—DR. BIRKETT delivered this address, taking as his subject, "The History of Medicine in the Province of Quebec" (see page 129).

Removal of Foreign Body from the Trachea.—Dr. J. H. BRYAN reported a case of a grain of corn removed from the trachea of a six-year old child. Several days before admission to the hospital he had inhaled the grain with the usual suffocative symptoms following, but these all quieted down and it was supposed that the body had escaped the air passages. Returning attacks of dyspnea seemed to disprove this assumption, but after admission to the hospital, a careful examination and a radiograph failed to reveal anything definite. Later respiratory signs were absent over the right lung but in a few hours air seemed to be entering freely on this side. Several ineffectual attempts were made to introduce a tracheal tube through the larynx but the swollen condition of the mucosa prevented. Just at this moment the child became cyanotic and stopped breathing. The trachea was immediately opened and the grain of corn was seen to pass the opening on its way to the lower trachea. It made several excursions to and fro before the operator was able to grasp it. The patient rallied well from the operation and the tube was removed on the fourth day. Some laryngeal stridor remained for a day or two longer. The grain of corn was a large one and had increased in size from absorption of moisture. Dr. Bryan said that the case showed that it was not always advisable to persist in passing a tracheal tube through a swollen larynx after several ineffectual attempts had been made. Irreparable injury might be done to the soft parts.

Personal Experience with the Bronchoscope, Esophagoscope, and Gastroscope.—Dr. THOMAS H. HALSTEAD of Syracuse, N. Y., read this paper. He had performed eighteen operations or examinations on fourteen patients, fourteen times under general anesthesia, and one without any anesthetic. Age varied from a newborn babe of two hours to a woman of seventy years. In four instances the operations were for the removal of foreign bodies; viz., penny in the esophagus of a five-year-old boy, bone in the bronchus of a woman, fish-fin in the trachea of an eight-months infant, spicule of glass in the larynx of an eight-months old infant, all being removed but the last. Of the remaining cases fourteen operations and examinations were for laryngeal papilloma, laryngeal stricture, papilloma of the lower pharynx, spasmodic stricture, suspected foreign body in the esophagus, three times on one patient for stricture and ulceration in the bronchus, once for relief of asphyxia in a newborn infant caused by pressure of enlarged thymus and thyroid glands, and four times for examination of the stomach for gastric ulcer or other lesions. The author referred to the pioneer work of Jackson through whose devices the stomach had been added to the organs capable of being examined directly by the eye.

Dr. EMIL MEYER of New York submitted specimens of foreign bodies he had removed during the last month by the bronchoscopic method. One was a grain of corn and the other the reed from a tin whistle. He laid stress on the point that vegetable bodies should be removed immediately whether symptoms were threatening or not. Delay caused such bodies to swell and might produce a local edema. He used cocaine in addition to a general anesthetic. Dr. Halsted's case was of special interest because it was probably the youngest on record. It was necessary in such work to have well-trained assistants.

Dr. H. L. SWAIN of New Haven reported two cases, one that of two false teeth from a portion of a dental plate swallowed by an epileptic. They had lodged in the upper part of the trachea for twelve hours and the consequent edema was so great that an immediate tracheotomy was necessary. The plate was finally removed through a Killian tube. A second case was that of a tin whistle which had gone down into the larynx and lodged in the trachea. It was readily removed by a Jackson's forceps.

Dr. E. FLETCHER INGALS of Chicago said that if a patient was suffering from severe dyspnea due to a foreign body one ought not to try upper bronchoscopy owing to the danger from the anesthetic. Tracheotomy should be done first and the body would often be coughed out, but if it should not be, bronchoscopy would be much easier through the glottis. Chloroform seemed to the speaker a better anesthetic than ether in this condition. He regarded the use of the galvanocautery in the bronchial tubes as dangerous. Bronchoscopy had a brilliant future, but it was not devoid of danger, and should always be done with the greatest caution.

Dr. W. E. CASSELBERRY of Chicago said it was possible to train patients to stand removal of papillomata through laryngoscopic methods. As to an anesthetic, ether should be supplemented with a hypodermic of morphine in order to control the laryngeal reflex. If the morphine was not used, he would prefer chloroform. He had never seen any bad results from the use of cocaine in addition to the general anesthetic.

Dr. A. COOLIDGE, Jr., of Boston said that in most cases a foreign body in the bronchus could be reached by upper bronchoscopy provided the necessary instruments and ability to use them were available; otherwise tracheotomy and lower bronchoscopy were indicated. The value of the upper operation for diagnostic purposes should not be overlooked.

Dr. H. P. MOSHER of Boston showed the following instruments: an esophageal speculum, an oval esophageal tube, a mechanical dilator for strictures of the esophagus, and a triangular laryngeal tube.

Dr. J. P. CLARK described a device he had employed for detecting the exact site of esophageal stricture. Before passing the esophagoscope, he had the patient take a glass of water in which was a silk thread, one end being fastened to the patient's face by a bit of adhesive plaster. On passing the tube, the thread could be followed down the gullet until it disappeared into a small opening of a pouch into which the tube went, thus showing the exact site of the stricture.

Dr. H. L. WAGNER of San Francisco spoke of the value of chloroform in these cases as administered per rectum.

Dr. J. M. INGERSOL of Cleveland had found the *x*-ray of value in preventing the recurrence of laryngeal papillomata.

Dr. HALSTED, in closing, said that in several instances his only assistant had been his office nurse. He believed that there was a great future for the investigation of the interior of the stomach by means of tubes. He had seen scars in the stomachs of two patients, had been able to detect inflammatory areas which he believed to be ulcers, and in one case had been able to see the pyloric opening, and even beyond.

The Form of the Hard Palate.—Dr. HARRIS P. MOSHER of Boston discussed the formation of the hard palate under the following scheme: (1) The four types of the hard palate: (*a*) well-rounded dental arch; the distance in a straight line from the center of the second molar on one side to a corresponding point on the other was about equal to the distance from either of these points to a point in the median line between the central incisors; the side lines formed a right-angled triangle. (*b*) Narrower than the above and shaped more like the three

sides of a parallelogram. (*c*) Angular, in which the sides of the arch were straight lines, not curved or bowed, and almost met in a point in front. (*d*) Much like (*a*) except that it was wider and larger. (2) The normal form of the palate. (3) The part played by the alveolar process in making the normal arch. (4) The causes of variation from the normal form which were (*a*) malocclusion of the teeth, (*b*) unequal growth between the parts of the septum, (*c*) low descent of the antra, (*d*) faulty shrinkage and readjustment of the premaxillæ, and (*e*) asymmetry of the halves of the palate. The central idea of the paper was that asymmetry between the halves of the palate was due not always to asymmetry of the head as a whole, but nearly as often to asymmetry confined to the bones of the face. The author believed that an explanation of fully one-half of the cases of asymmetry of the hard palate was to be found in the faulty eruption of the teeth, the anterior teeth as well as the posterior, and in their faulty occlusion. We should therefore look after the proper eruption and spacing of the teeth and should call the dentist to our aid.

Dr. D. Bryson Delavan of New York said he had never been able to understand why we found the high arch palate so early in life. Occasionally it was present at birth, certainly often before dentition, and before we were able in any way to prevent it.

Dr. A. Coolidge, Jr., said that the face contained three sets of cavities: the mouth, orbits, and nasal fossæ. The functions of these cavities demanded accurate adjustment of their parts. The cavities were so closely packed together that deformity of one tended to cause deformities in the others. Asymmetrical accessory sinuses he believed to be often a secondary effect rather than a primary cause of deformity, a correcting rather than a deforming factor. Whatever departures from typical growth we might prove or guess to be due to this factor or that, we could often trace the counteracting asymmetrical growth, attempting to minimize the disturbance of function which deformed jaws or deviated septum or a flattened orbit would cause.

Dr. B. Alexander Randall of Philadelphia thought that the element of heredity was a prominent factor in many of these cases.

Dr. John O. Roe of Rochester called attention to recent views expressed on this subject by various dentists. He said that the effect produced by the open mouth was a narrowing of the jaws by the lateral pressure of the muscles of the face that were drawn more or less tense. There was also the absence of the opposing pressure of the teeth against each other which greatly assisted in maintaining their regularity during the period of their eruption. In the closed mouth the tongue also played an important part in keeping the jaws, particularly the upper jaw, properly expanded.

Dr. D. Braden Kyle of Philadelphia said that irregularity in development seemed to be largely confined to the upper jaw. This would indicate that nutrition played an important part in the development of these two structures. The blood and nerve supply of the upper jaw came largely through bony foramina. Might it not be possible that until a certain age these bony openings were sufficiently large to permit sufficient blood and nerve supply and that then from some slight injury or malformation their size was interfered with and they became relatively too small for the proper nutrition?

Dr. Mosher, in closing the discussion, stated that the probable explanation of the high arch before the second dentition was the faulty shrinkage of the premaxillæ. They might swing down into proper position but did not shrink. Owing to this their vertical diameter was greater than normal. Therefore in order for the posterior teeth to attain the level set for them by the anterior teeth, they must grow downward farther than usual. For these reasons the arch was high from the start.

Cyst of the Frontal Sinus Communicating with the Frontal Lobe.—Dr. Clement F. Theisen of Albany, N. Y., reported a case of this nature occurring in a woman of 34 years who had had, following a severe fall in childhood, severe head pains on the left side with a discharge from the corresponding naris. There were pressure and fullness over the eyes, some ptosis of the left lid, but no displacement of the globus. Transillumination seemed to justify an opening of the left frontal sinus, when a fluctuating tumor suggesting a cyst presented at the opening. Much thin mucus escaped when it was opened, but this unfortunately was not examined. A considerable portion of the posterior wall of the sinus was missing and the cyst appeared to extend through to the frontal lobe. Pulsation of the meningeal vessels could be seen. The patient made a good recovery and ten months after operation she was well and free from headaches. The author referred to similar cases reported by Logan Turner and other writers. The literature on the subject was scanty.

Notes on Two Interesting Cases of Frontal Sinus Disease.—Dr. J. Price-Brown of Toronto reported the cases. The first patient was a girl with right frontal abscess on whom a previous operation had been done leaving an open fistula which discharged from time to time. Dr. Brown opened the sinus and chiselled out a rectangular piece of bone from the outer table, curetted the cavity, and made a free opening down into the nose external to the septum and in the region of the anterior end of the middle turbinal. A gold tube was then inserted from above and the wound was closed. Healing was satisfactory but it was found impossible to irrigate the sinus through the tube. The discharge from the old fistula did not entirely cease, consequently twenty days later another operation was done embracing the area of the fistulous discharge. Some bits of dead bone were removed, and a rubber tube was substituted for the gold one, the outer incision being closed as before. Healing was satisfactory and the discharge entirely ceased. The author thinks that the wearing of the gold tube for the interval between the two operations secured a dilatation of the passage into the nose which afforded permanent and effectual drainage. The second case was one of frontal sinus disease occurring in a man and following an injury. Several months later evidences of sinus involvement were evident and he came under observation with symptoms of acute trouble calling for immediate relief. Intranasal treatment failed to give the desired benefit so the sinus was opened into above the superciliary ridge and the anterior cells of the ethmoid were destroyed by drilling, a rubber drainage tube was introduced as before, after the sinus cavity had been thoroughly curetted. The outer wound was closed and intranasal irrigation practised. Examination of the sinus contents revealed a pure pneumococcus infection. The wound did not heal by first intention and it was necessary to open it. Granulation commenced and irrigation was carried out through a small rubber tube inserted down into the nose. This tube was eventually removed and healing was in the end satisfactory. Much benefit resulted from the use of the reversed Valsalva procedure in removing discharge during healing, from the frontonasal passage. While in both cases the anterior ethmoid cells were engorged and the middle turbinal pressed tightly against the septum, in neither case was there any indication whatever of involvement of the maxillary antra.

Sinusitis Pyemia; Severe Cerebral Symptoms Relieved by Operation; Death; Autopsy.—Dr. Lewis A. Coffin of New York reported a case in which the sequence of events was expressed by the title of his paper. His patient was a woman of 33 years who was admitted to hospital with unconsciousness, delirium, and convulsions. There was an orbital cellulitis on the right side of the head with swelling of this entire side, and it was believed

that there was an empyema of the frontal and ethmoidal sinuses; furthermore that there was a commencing right-sided meningitis. It was later learned that she had been ill about a week. A Killian operation was done without incident except that the pus was found under high pressure. The bone of the posterior sinus wall appeared healthy. She did well for a few days but her temperature continued elevated and a radical Caldwell-Luc operation was done on the right antrum which was found filled with polypi. About this time the woman aborted with a three months fetus. Later, infection spread from the uterus, and various small swellings appeared on different parts of the body. These were opened and finally the patient seemed in fairly good condition. Later hemiplegia developed and brain abscess was suspected. Puncture just back of the frontal sinus at the roots of the hair evacuated considerable pus. Convulsions followed and she died two months after entering hospital. Autopsy revealed the entire right hemisphere covered with a thick purulent exudate on the inner surface of the dura which was firmly adherent to the pia-arachnoid. The opening of the abscess cavity, which extended down into the white matter, was on the superior surface of the right frontal lobe about midway between the anterior pole and the fissure of Rolando, lying in the superior frontal fissure, and involving the contiguous parts of the superior and middle frontal convolutions. The author thought that the bone was infected when the patient entered the hospital and that an osteomyelitis and pyemia had already begun.

Dr. W. E. Casselberry referred to the difficulty in such cases as that of Dr. Theisen of making a differential diagnosis between true serous disease and serous exudate into a bony cavity. There was also great confusion in the nomenclature, as some writers used the term serous cyst, and others mucocele. Perhaps this was of greater importance in the antrum than in the frontal sinus. We had there the connection between dental cysts which were more common in the antrum than the similar cystic formation in the nose.

Dr. H. P. Mosher noted that sinus cases fell into two classes of chronic retention and chronic suppuration. There were many grades of mucocele, from the case in which but few of the mucous glands were diseased and but little mucus was poured into the sinus, to that in which all the glands were diseased and the cavity was completely filled with secretion. The larger the amount of blood in such a cavity, the more easily would it become infected. Many a case of chronic suppuration was originally one of mucocele complicated with partial or complete hematocele. He would regard Dr. Theisen's case as one of uninfected mucocele.

Dr. H. L. Swain thought that sinus conditions were exactly similar in their pathological significance to aural conditions and that the use of the terms serous, mucous, and purulent would be sufficient for a clear terminology.

Dr. C. P. Grayson of Philadelphia questioned the advisability in such cases as had been reported by Dr. Price-Brown of introducing tubes to secure permanent drainage. If Laurens' method was followed by the opening of the frontal sinus and the removal of the anterior wall with thorough curettage of the cavity and breaking down of all the anterior and posterior ethmoidal cells, gauze could be carried down into the nose and the external wound closed. Packing could be removed in 36 or 48 hours. He himself had not observed any great tendency to contraction of the drainage channel.

Dr. J. H. Bryan believed that there was a very great tendency to closure of the channel between the frontal sinus and the nose.

Dr. T. P. Berens of New York said that the whole proposition could be expressed in the statement that the success of any operation upon the frontal sinus depended upon complete drainage and this could be secured only by complete removal of the anterior ethmoidal cells.

Dr. L. A. Coffin referred to a case of large retention cyst causing exophthalmos. On opening the anterior ethmoid cells by resection of the frontal process of the superior maxillary bone, he found a cavity as large as an English walnut the contents of which were sponged out in one gelatinous mass. The orbital wall was necrotic and the cavity connected with the orbit. As to drainage tubes, they were unnecessary in the Killian operation. He had been called on to do a secondary operation but once and that was owing to the overlooking, in the primary intervention, of a very narrow supraorbital recess.

Hyperplasia Lateralis Linguæ; Papillitis Atrophicans Bilateralis Linguæ.—Dr. Henry L. Wagner of San Francisco reported these two cases. The first was that of a man of forty years, an inveterate cigarette smoker with some dental defects and a narrowed lateral diameter of the lower jaw. There was a hyperplasia of the superficial structures of the side of the tongue with similar pathological conditions of both lower turbinals. The patient particularly complained of a lancinating pain caused by a very small ulcer in the center of the hyperplastic lingual tissue. A thorough extirpation of the area complained of relieved all symptoms. Microscopical examination of the tissue removed showed a true hyperplasia of all the layers of the mucosa.

The second case was that of a woman of 54 years with small whitish vesicles similar to herpes, on the left side of the tongue, recurring at regular intervals and accompanied by general malaise. A few days subsequent to each attack a subacute inflammation followed. Bilateral atrophy gradually set in, but a prolonged iodide treatment had prevented recurrence for nearly a year. The microscope showed a thinned but dense epithelial layer, a deeper layer corresponding to the rete mucosum and a loose fibrous structure of the corium with almost complete obliteration of the secondary papillæ. Few mucous glands remained. No lump or nodule appeared in the tongue. The condition suggested, but for the atrophy, the parenchymatous hemiglossitis described by Butlin.

Dr. J. P. Clark asked how Dr. Wagner would rule out pemphigus of the tongue as a possible diagnosis in his second case.

Dr. J. H. Bryan thought that one did not get atrophy with pemphigus in this situation.

Dr. J. W. Farlow had seen several cases of pemphigus of the mouth, but in that disease the eruption is bullous and not vesicular as in Dr. Wagner's case. He had not seen atrophy follow bullæ and would not consider this case as one of pemphigus.

Dr. Wagner admitted that the examination made at the time of eruption did not coincide with all the desiderata for a diagnosis of pemphigus and he had simply left this question open, being glad to have light thrown on the matter.

Sarcoma of the Tonsil.—Dr. J. Edwin Rhodes of Chicago reported a case in a man of 35 years whose symptoms had begun some six months previously with pain at the angle of the jaw. He had lost flesh, retained his appetite, but had some difficulty in swallowing on account of the size of the growth. Recently he had had attacks of dyspnea, also slight bleeding from the mouth. No external glandular enlargement could be made out, but a growth ran from the left tonsil two-thirds of the way across the fauces. It was pinkish, lobulated, easily penetrated by a smooth flat probe and showed blood-vessels indistinctly over its surface. Removal was determined on and the external carotid artery was first tied on the left side, local anesthesia being used. This was a difficult operation as in order to breathe the patient had to keep his head flexed and chin lowered. Following this, cocaine and adrenalin were injected freely into the base of the tumor through the anterior pillar. The mass was gradually enucleated but owing to the patient's retching it had to be removed in fragments in several attempts.

Recovery was without incident except that a small ligature abscess occurred. The microscopist reported round-celled sarcoma of the alveolar type. One month after operation the patient had a small mass in a new site on the lateral wall of the pharynx behind the posterior pillar. No second operation was deemed immediately necessary and as the patient was leaving for his home city, he was advised to use the *x*-ray treatment and if possible to take the Coley toxins. He was reported as doing well, but in view of the laboratory findings, Dr. Rhodes did not feel optimistic as to the eventual cure.

Dr. D. Bryson Delavan of New York referred to the starvation treatment of such growths as elaborated by Dawbarn. It was quite possible that ligation of the carotid would be an advisable procedure before the extirpation of such tumors as the one described by Dr. Rhodes. Even if it did not result in cure, we would still have the alternative of the more extensive operation.

Dr. Rhodes replied that he would not expect much from such a procedure as ligation of the carotid as owing to the quick reestablishment of the collateral circulation, the inhibition of the growth would not result. The call for immediate operation in his own case was on account of the size of the tumor.

Dr. B. Alex. Randall of Philadelphia had noted in a ligation such as that described by Dr. Rhodes, entire absence of pulsation in the temporal artery for sixteen days. This would give some idea as to the time required for the reestablishment of collateral circulation.

The Influence of Adrenalin in the Causation of Arteriosclerosis.—Dr. Frederic E. Hopkins of Springfield, Mass., gave a review of the literature of the last four years. He found that the unreliability of animal experimentation vitiated many of the conclusions drawn as to the deleterious effects of the remedy on the vascular system. Moreover it had been shown that large doses could be given continuously to patients without causing arteriosclerosis. He therefore felt that there was ample ground for reassurance in the reasonable use of the remedy.

Dr. C. F. Theisen of Albany said that recent experiments had shown that atheroma of the vessels was usual only when the adrenalin was injected intravenously.

Dr. Harris P. Mosher had made some experiments on guinea pigs, but in no instance did adrenalin applied to mucous membranes in the nose have any effect on the aorta.

Dr. B. Alex. Randall of Philadelphia had used adrenalin with benefit on cases of exophthalmic goiter and in otitic vertigo. He had never seen any result on the vessels. He preferred for the conditions named the dessicated adrenals in doses of two or three grains, using the adrenalin chloride only as an emergency preparation which could be taken instantly at the first threat of trouble.

Recurrent and Abductor Paralysis.—In the symposium on this subject Dr. J. W. Gleitsmann of New York read a paper on the Etiology from Central Causes (see p. 12); Dr. D. Bryson Delavan of New York one on the Etiology from Peripheral Causes (see p. 92); Dr. Clarence C. Rice of New York a paper on the Symptomatology (see p. 220), and Dr. W. E. Casselberry of Chicago one on the Diagnosis and Treatment (see p. 303).

Dr. E. Fletcher Ingals said he had found some difficulty in making a diagnosis of aneurysm in this form of paralysis in so far as the *x*-ray plate was concerned. He had noted invariably on the plates a darkened area just at the left side of the esophagus due presumably to the large arteries. In two instances he had seen distinctly a small tumor just at the left side. He had thought that these swellings might be small aneurysms, but autopsy in one case had failed to show any such condition. He would like to inquire of those present if they had had any such experience.

Dr. G. Hudson Makuen said the interesting point was to determine the exact location of the lesion causing the paralysis. Three possible locations had been suggested in the papers presented, (1) in connection with peripheral organs, (2) in the medulla, and (3) in the cerebral cortex. He was sceptical in regard to the last named for he did not recall an authentic case of abductor or adductor paralysis due to cortical disease. The fact that stimulation of the cortical centers would cause to-and-fro movements of the cords did not prove to his mind that a lesion in such a center would cause true cord paralysis. It merely meant that stimulation of those cortical segments might incite the bulbar motor centers to action and thus cause the to-and-fro movements. In over 2,000 cases of patients with gross defects of speech he recalled only one paralysis of a bulbar origin and it was a case of unilateral abductor paralysis.

Dr. B. Alex. Randall had had under observation a man with total cord paralysis from a cortical tumor, the removal of which had been successfully accomplished, but as yet with only slight return of power in the cord. A more perfect demonstration of a cortical lesion as the cause of the paralysis could hardly be seen.

Dr. H. L. Swain had seen three cases with inspiratory dyspnea due to paralysis of the abductor muscles, but in all a local lesion had been found. In two it was a syphilitic immobilization of the cricoarytenoid joint and in one, which eventually came to autopsy, it was due to a complete necrosis of the cricoid cartilage.

Dr. J. O. Roe referred to a case of laryngeal paralysis due to a fusiform enlargement of the aortic arch. He had seen a number of cases of left side paralysis due to tuberculous deposit at the pulmonary apex.

Dr. C. P. Grayson referred to a case under his care during the past winter, that of a man with dyspnea and noisy stridor. Examination by every known method was without result as to the discovery of a cause, but the dyspnea became so great that a tracheotomy was called for. Later it was learned that he had had two or three attacks of peritonsillitis the year previous. Whether such a lesion might be the cause of a peripheral neuritis or not, he could not say. The lesion in the larynx was a double abductor paralysis which might have resulted from a toxic neuritis in connection with the quinsies.

Dr. C. F. Theisen said that the *x*-ray was often of no service so far as a conclusion as to the cause for compression of the recurrent laxyngeal was concerned. In one instance sudden death had resulted from compression not only of this nerve but also of the pneumogastric in a mass of enlarged glands, although the diagnosis of aortic aneurysm had been made.

Dr. Gleitsmann, in closing, wished to point out certain interesting facts. It was highly desirable that we should be more definite in our expressions and discussions when referring to laryngeal paralysis. As to the existence of cortical paralysis he would say that bilateral adductor paralysis in hysteria, etc., was of the cortical type. He agreed that the presence of a recurrent or abductor paralysis did not in many cases assist us in the diagnosis of the lesion which produced it. Patients might recover from laryngeal paralysis though this was very uncommon. Of recovery from bilateral recurrent paralysis, but one case was known. Here the paralysis had been caused by large pericardial exudates on both recurrent nerves and had disappeared with the absorption of the fluid.

Dr. Delavan stated, in closing, that very few of us realized the varieties of causes which might produce this form of paralysis by pressure. Aneurysm was always thought of, but other possible causes were overlooked. The *x*-ray had proven of very great value, and no obscure case should be dismissed without recourse to it. Cricoid ankylosis was often mistaken for paralysis.

Dr. Casselberry believed that the larynx had been neglected of late years and that such discussions as the one now taking place were of the utmost benefit. He was disposed to place high value on the *x*-ray picture as an aid in the diagnosis of aneurysm. When one saw a projection on

the plate and a pulsation with the fluoroscope a diagnosis was reasonably positive. As to diagnosis *intra vitam* of degeneration inside of the medulla we could only make it by observing similar cases which ultimately came to post mortem and in which degenerated areas were found in this particular place. He was opposed to intubation in cases of abductor paralysis because he thought it was dangerous to teach the patient to rely upon the tube. If the tube was expelled the patient might die before it could be reinserted. Cures reported of laryngeal paralysis might be cures of only ankylosis.

(To be continued.)

THE AMERICAN GYNECOLOGICAL SOCIETY.

Thirty-third Annual Meeting, Held at Philadelphia, Pa., May 26, 27, 28, 1908.

The President, Dr. J. Montgomery Baldy of Philadelphia in the Chair.

After an Address of Welcome by Dr. Edward L. Duer of Philadelphia, which was responded to by Dr. William M. Polk of New York, the scientific work was begun.

Immediate Versus Deferred Operation for Intra-abdominal Hemorrhage Due to Tubal Pregnancy.—Dr. Florian Krug of New York said that whenever there were opinions diametrically opposed to each other on mooted points in surgery, the truth as well as the best interests of the patient would not be found at either extreme, but in the middle. It could not be conceded that in any case of ectopic gestation operation should be deferred for as long a period as it recntly had been recommended by some, nor should the patient be subjected to a hasty operation in every case even when the diagnosis had been established beyond a reasonable doubt. The severity of shock was not always proportionate to the amount of blood lost. Comparatively few patients died from actual hemorrhage. In most cases termed "tragic" or "cataclysmic," the hemorrhage had been seriously aggravated by trauma (curettage), too vigorous bimanual palpation, etc. Some patients would die before surgical aid could reach them, others would die in spite of it, and some had died because of it, surgical interference having taken place too hurriedly, without proper preparations.

Dr. F. F. Simpson of Pittsburg said that the first hemorrhage was rarely severe. This was the time for diagnosis and for operation as early as elective conditions could be brought about. The teaching that death was imminent when rupture occurred, made the inexperienced treat the affection lightly until the occurrence of a second or third hemorrhage, which might indeed be alarming. If the patient was almost exsanguinated, very little additional depression would wipe out her margin of reserve strength. With simple, prompt, and proper treatment such as any practitioner should be able to give, hemorrhage from rupture should rarely cause death. The decision for immediate operation should rest upon a low mortality for such operations in the individual operator's hands rather than on an essentially high mortality which the disease had been supposed to have.

Dr. Hiram N. Vineberg of New York said that the amount of intraperitoneal hemorrhage varied within wide bounds. In the majority of cases it was not so great as to be a direct menace to life. Operative treatment might be as early as was feasible or deferred a few days to suit the convenience of the operator and the exigencies of the surroundings. In a very small percentage of cases the hemorrhage was so great as to be a direct menace to life from anemia and from pressure upon the diaphragm and consequent crowding of the heart and lungs. These had been termed by the writer "cataclysmic" cases from the sudden onset and from the rapid inundation of the abdominal cavity with blood. Immediate operation in this class of cases was imperative and, if aided by intravenous saline infusion, expeditiously and skilfully administered, would save an otherwise doomed life. The accompanying shock formed no contraindication to surgical intervention for the purpose of arresting any further bleeding and to relieve the great intraabdominal pressure upon the heart and lungs. In cases of postoperative hemorrhage one would not be deterred from intervention because the patient was in shock from having just undergone a serious operation, and the same would apply to the shock attending a very copious intraperitoneal hemorrhage from rupture or abortion of tubal pregnancy.

Dr. C. C. Frederick of Buffalo said that the necessity for a decision to be made between immediate and deferred operation for intraabdominal hemorrhage due to tubal pregnancy was quite rare, or had been in the writer's experience, owing to the fact that diagnosis of the existence of ruptured tubal pregnancy by the family physician had been made late, seldom within the first three or four days after primary rupture, and often as many weeks thereafter. Out of about 125 cases of ruptured tubal pregnancy the writer had seen, in only six cases the hemorrhage immediately following rupture was large enough to endanger the life of the individual. Three were *in extremis* when first seen and were immediately operated upon, every possible means of stimulation being used meanwhile to tide them over the operation. Operation was rapidly done, but all died from shock. In the fourth case he decided to stimulate and wait. This woman also was *in extremis*, almost pulseless, ten hours after rupture. She did not rally and died three hours after he first saw her. The fifth case was seen about two hours after rupture; patient's pulse was countable at 120; both heart sounds were quite clear, but the patient was much shocked. He advised stimulation and normal salt solution subcutaneously. The patient rallied for a time, but began to fail in another hour and, the speaker being busy with other work, another surgeon was called in and at once operated, saving the woman's life. A sixth case, operated upon about five hours after rupture, while suffering much from shock, made a good recovery. It therefore appeared, from his experience, that only about five per cent. of ectopic pregnancies were accompanied by a dangerous hemorrhage at time of rupture. In the remaining 95 per cent., as the result of shock and lowered vascular tension, together with the small size of the vessels torn, the bleeding was normally controlled, at least temporariiy, by coagulation. Later, when vascular tension again arose and the patient began to move about, the hemorrhage might and generally did recur. When we were brought face to face with a rupture it was necessary to decide whether this specific case was one of the 95 per cent. which would be self-limited or one of the five which would kill the woman. The condition was much like acute appendicitis; we never knew at the beginning what was going to happen. It had always seemed to the writer that bleeding, whenever endangering a patient's life, should be controlled, if possible. It was a surgical principle from which it was difficult to get away. It therefore had always appealed to the writer to be a good principle to open the abdomen in these cases as soon as seen, using all possible known means of stimulation during the operation, that is, if the patient's condition was one of danger; otherwise, if the patient did not show profound shock from hemorrhage, he should advise waiting till she rallied.

Dr. E. E. Montgomery of Philadelphia said that the one ever-dreaded termination was that of internal hemorrhage, which might be slow and small in amount, or so profuse as to threaten life and even cause the death of the patient. Hemorrhage might occur in one of four ways: (1) It might be the result of rupture of the tube, either into the peritoneal cavity, when it was free and might be excessive, or into the broad ligament and was necessarily limited in quantity; (2) the development of the embryo within the

tube might so thin its walls that the chorionic villi would project through pinhole perforations and cause dangerous and continuous hemorrhage; (3) a partial separation of the embryonic sac might occur and hemorrhage fill the tube escaping from its abdominal end and through the uterine end into the uterus. In this form the clotting took place early in the tube and the quantity of blood lost was slight; (4) the fetus and its envelope might be forced through the abdominal end of the tube into the peritoneal cavity—a tubal abortion. This accident was not infrequently associated with very profuse bleeding. In the majority of cases of ectopic gestation, the hemorrhage if untreated would not prove fatal. Very rarely, in the cases formerly supposed to have been cured by the systematic employment of the galvanic or faradic current, was the fetus alive at the time of the application, the fetus having already met death through the rupture of the sac. The symptoms regarded as diagnostic of ectopic gestation were those incident to rupture, as diagnosis prior to rupture was not then regarded as possible. The electrical treatment, consequently, was applied to the pelvic collection of blood resulting from the rupture and the cure consisted in the removal or absorption of the clots. It was doubtful whether the absorption under the treatment was any more expeditious than it would have been had no treatment been employed. With the shock and diminished arterial tension incident to the rupture of a tubal gestation-sac, and the tendency to the formation of a clot, the probability of the arrest of hemorrhage was increased. In many cases this arrest occurred before a hemorrhage of any severity had ensued, and the patient so rapidly recovered from the indications of an internal hemorrhage as to leave the diagnosis in doubt. That fatal hemorrhage occurred from ectopic gestation had been too well demonstrated to admit of denial. The records of the coroners' physicians of all of our large cities and the experience of many physicians had abundantly proven this. In such cases prompt action would prove the sheet-anchor. It was just as important that the bleeding tubal vessel should be secured as if a vessel of equal size upon the surface were the cause of the hemorrhage.

Dr. Egbert H. Grandin of New York gave a résumé of his personal experience. He believed that the abdominal route was the only rational, logical, and safe one except in the formation of hematocele, or for the purpose of diagnosis, when the vaginal route should obtain. He looked upon ectopic pregnancy as the most malignant disease to which woman was subjected, posibly excepting carcinoma, and the malignancy increased in proportion as the surgeon sat on the fence and waited. When the woman was in deep shock, the active hemorrhage had ceased, and we should therefore wait until she had rallied, and then go in, always by the abdomen. When bleeding was going on he did not believe one should stimulate the patient until the abdomen had been opened and the source of the hemorrhage checked. Stimulation, especially intravenous, simply heightened blood pressure and made the woman bleed more. In hematocele formation he believed the surgeon should operate by the vagina and clean out. If the condition of the patient permitted, he would open the abdomen and exsect the damaged broad ligament.

Dr. A. Lapthorn Smith of Montreal said that there was only one treatment for tubal pregnancy, and that was early removal. If rupture had taken place the case became an emergency one. Even if the patient was unconscious from shock (hemorrhage), he would not wait until she had rallied, for this would mean a fresh hemorrhage, but he advised cutting down and tying the bleeding vessel, replacing the blood that was lost with normal salt solution.

Dr. B. F. Baer of Philadelphia said it was always imperative to act at once, secure and close an open bleeding vessel, and this held true in hemorrhage from a ruptured tubal pregnancy. But there may be a doubt in a certain case of very profound collapse whether the vessel was still open and whether it might not be wise to spend a few hours in restorative measures.

Dr. August Martin of Berlin said there was no necessity for operating on these cases hastily if hemorrhage had ceased, but if bleeding was still going on we should follow the surgical rule to operate with a view to stopping the hemorrhage. As to whether the operation should be done at the residence of the patient or not depended on circumstancs, but preferably the surgery should be done at a hospital. If the case was urgent, operation should be done immediately and by the abdominal route, but in less severe cases the vaginal route could be selected.

Dr. Seth C. Gordon of Portland, Me., quoted the dictum of Lawson Tait that "no man living ever made a diagnosis of extrauterine pregnancy before rupture." In 1887 a pupil of the speaker telegraphed him to the effect that he had a case of extrauterine pregnancy and desired Dr. Gordon to be ready to come and see the patient at a moment's notice. Two hours later rupture took place, but it was twelve hours after rupture had taken place before the speaker saw the patient. After opening the abdomen he removed four quarts of bloody fluid and a fetus, which was about ten or twelve weeks old. The woman made a good recovery. He mentioned three other cases he had operated on after rupture had taken place, with recovery of all the women. He recalled only two cases in which he was able to make a diagnosis before the occurrence of rupture, and these were operated on promptly and both women recovered.

Dr. E. W. Cushing of Boston said his attention had been called to this subject some twenty years ago by a case in a near relative. Those who were old enough would recall many cases of so-called hematocele which got well, and he doubted whether women had tubal pregnancy any oftener to-day than they had in 1888. Notwithstanding this, he believed in operating on these cases, and yet he had seen several patients whose symptoms of tubal pregnancy with or without rupture were so slight and so obscure that it was not easy to obtain consent to operate. He mentioned two cases upon which he had operated within two months, the operations having been followed by the recovery of both patients.

Dr. Hunter Robb of Cleveland said that more conservatism in the treatment of ectopic pregnancy was called for in the majority of cases. When the diagnosis of ectopic pregnancy was certain, operative measures were indicated; but in most cases the danger was not sufficiently imminent to warrant immediate interference unless the condition of the patient was otherwise satisfactory. Many women not only survived the effects of a tubal abortion or rupture, but also recovered even without an operation. When a patient was seen in a case of collapse as the result of a ruptured ectopic sac, she should not be operated on until the condition of shock had been tided over. These patients, when they died, usually succumbed not from loss of blood, but mainly from shock. Why, then, should we superadd to the original shock the shock of a major operation, with all the exhausting preliminary procedures? In support of the view that these patients died from shock and not from loss of blood, we had clinical observations of good authorities, and also experiments on animals. Physiologists taught that a woman weighing 130 pounds must probably lose four pounds of blood before succumbing to the effects of the hemorrhage *per se*. So large an amount of blood was rarely found in the abdominal cavity; the bloody fluid was a mixture of blood and a serous exudate. The sudden removal of a large quantity of recently accumulated fluid in the abdomen before the other vessels had time to adapt themselves to the altered mechanical conditions was dangerous and might be followed by fatal syncope. Patients in whose cases the bleeding would be sufficient to cause death were rarely seen in time to be saved by an operation for ligating the bleeding vessel. The best operators gave a percentage of 40 or 50 as their death rate after immediate operations during shock. The deferred operation had given

better results in the hands of equally good operators. So long as there was a reasonable evidence that immediate operation might be the wrong procedure, it was the duty of the physician to hold his hand and leave something to nature.

Dr. J. Wesley Bovée of Washington, D. C., said that there could be no doubt but that if some of the cases of tubal pregnancy were allowed to go without operation the patients would die from a subsequent hemorrhage. No case was safe without operation. He preferred the abdominal to the vaginal route.

Dr. Andrew F. Currier of New York agreed with those who had said that these cases were surgical, and just as a surgeon would endeavor to stop a hemorrhage that occurred from a bleeding vessel in any portion of the body, so was it equally important and proper to stop it in cases of tubal pregnancy.

Dr. Hugo Ehrenfest of St. Louis said he had operated on a woman a few weeks ago in whom infection had occurred from a well formed hematocele from an attempt to perform a criminal abortion on herself. She was three months advanced in pregnancy. A diagnosis of infected hematocele was made from the presence of a mass and septic fever. Operation confirmed the diagnosis.

Dr. F. Pfannenstiel of Germany said there were a few rare cases in which hemorrhage was so great that they must be operated on promptly in order to save the lives of the patients. He thought we should operate as early as possible without precipitation.

Dr. Brooks H. Wells of New York said that while in cases of ectopic pregnancy 95 per cent. might get well without operation, and that 5 per cent. surely died without being operated on, the best results could be obtained by operation done just as soon as the diagnosis could be made. Those women who made the quickest and smoothest convalescence, and who had the fewest symptoms of trouble afterwards, were the ones who were operated on quickly. Furthermore, the mortality rate in those operated on promptly was much smaller than in those who had been in "cold storage" for days or sometimes weeks.

Dr. Joseph Taber Johnson of Washington, D. C., said it was a backward step to wait and see whether these patients were going to bleed again or not. The proper thing to do in these cases was to operate, and the sooner the ruptured tube was removed the better.

Dr. William Gardner of Montreal believed that the majority of cases should be operated on, but the question arose should not the gynecologist wait or operate immediately. He thought Professor Pfannenstiel sounded the keynote when he said we might operate, but without precipitation. He would wait in certain cases, but watch them carefully, before deciding to operate.

The Heart in Shock.—Dr. Eugene Boise of Grand Rapids, Mich., said it was generally conceded that the element of danger in shock was the very low blood pressure. It was also generally believed that the cause of this low blood pressure was vasomotor paralysis. Dr. George W. Crile adopted this theory as the result of a large number of experiments. The author thought that the conclusion of Dr. Crile was erroneous. Dr. Howell spoke of a cardiac shock in which the low blood pressure was due to cardio-inhibitory exhaustion. Dr. Yandell Henderson thought that shock was due to a deficiency of carbon dioxide in the blood, and that when death occurred suddenly in shock the heart was tetanically contracted. A series of experiments had apparently demonstrated that in shock the heart was in a state of tonic contraction, the degree of which varied with the degree of shock, and that treatment directed to the relief of this condition was the correct treatment for shock.

Pernicious Anemia in Pregnancy.—Dr. Palmer Findley of Omaha, Neb., in a paper on this subject reviewed the literature and then presented a clinical report of a case with the post-mortem findings in both the mother and child. As a result of his observations, he presented the following summary: "(1) Pregnancy and the puerperium exercise a favorable influence on the development of pernicious anemia. (2) Women are more liable to pernicious anemia during pregnancy and the puerperium than at any other time. (3) There was no satisfactory explanation for the effect of pregnancy upon the development of pernicious anemia. Frequent child-bearing, prolonged lactation, overwork and malnutrition were predisposing factors. (4) There was a remarkable uniformity in the clinical phenomena and post-mortem findings. (5) The onset of anemia was usually in the latter half of pregnancy. (6) The diagnosis was not possible at the onset, but was later determined by exclusion of other possible forms of anemia by blood examination, fatal termination, and finally by post-mortem examination. (7) The child usually died *in utero* or shortly after birth and had never been observed to show pernicious anemia. Spontaneous interruption of pregnancy was the rule. (8) In all well established cases the disease had proven fatal."

Suggestions in Teaching Gynecology.—Dr. John A. Sampson of Albany, N. Y., demonstrated special mechanical charts as an aid in this work, and said that three phases in the study of any of the clinical branches of medicine naturally suggested themselves: First, the study of each disease as a science, namely, its cause, the changes in anatomy in its different stages, and, particularly important, the explanation of its symptomatology. Second, the classification of symptoms and the study of the various causes of each symptom and how these causes may be differentiated. Third, the art or technique of the clinical branch of medicine, namely, taking of the history, physical examination, diagnosis, and treatment, and importance of clinical experience on the part of the student in the dispensaries, wards, and hospitals, or in private practice. The conditions caused by each disease, which are illustrated problems, the student should attempt to solve from his knowledge of normal anatomy, normal physiology, etc., instead of memorizing data obtained from lectures or textbooks. In the solution of these problems questions were asked, and the answers of the student corrected when necessary and supplemented by information which he could not be expected to reason out. Various means may be employed, such as drawings, models, actual specimens removed at operation or at post-mortem, using whichever means were best adapted to the special subject under consideration. Mechanical charts were of great value in this work.

Hospital Gynecology.—Dr. Robert L. Dickinson of Brooklyn, N. Y., spoke of gynecology as a separate department and described the character of hospital as affecting this. He pointed out the need of a working adjustment between surgery and gynecology, and spoke of the relations which should exist between the assistants and the house staff. He thought there should be uniformity in technique where the operators were numerous, and believed there should also be standard schedules of preparation, of outfit, of after-care, etc. He then discussed the methods of exhibiting or guarding the histories of cases in wards, and pointed out the interrelation of hospital and dispensary.

Operations for Relief of Pelvic Diseases of Insane Women.—Dr. Leroy Broun of New York said that in 1902 he was placed in charge of the gynecological operations of the Manhattan State Hospital, an asylum having under its care some 2,500 women and receiving yearly about 1,000 new patients. All patients on admission were given a systematic physical examination, including the condition of the abdominal and pelvic organs, each feature of the examination being carefully carried out by one trained in the special line. When pelvic or abdominal pathological conditions were present such patients were referred to him for the purpose of determining whether symptoms arose from such, and if so whether an operation would be of benefit. The advisability of an operation having been de-

cided on, the guardians of such patients were communicated with, the condition and physical benefits were explained, and their approval of the operation considered advisable was asked. When refused, as not infrequently happened, nothing was done. Since his connection with the hospital there had been done by himself and under his supervision 411 abdominal and pelvic operations. In 1905 he presented for consideration a paper based on the surgical work performed on these unfortunates during the two years previous. The conclusions drawn were: That in no instance was the mental disturbance of the patients accentuated by the operations performed; that the physical benefit shown by those operated on was noticeable in a marked degree in almost 50 per cent. of the cases, and appreciable in about 40 per cent. As a result of this bodily improvement they became happier and more contented units of the colony in which they lived. The mental recovery of 20 of those included in this preliminary report was unquestionably hastened by the operations performed upon them. While in most instances there had been some mental improvement before the operation, yet in all of the 20 the psychic improvement was striking after the surgical recovery and in some instances the improvement seemed to date from the operation. Three years had passed since the preliminary report of this work. The number of patients included in the present report was 411. This included the total number operated on for the last five years. Of this number 72 patients had been discharged as recovered. The mental recovery of 32 of this number, or about 44 per cent., showed a much more rapid improvement after the operation than before. No patient was included in this number whose mental progress was not marked after the operation in comparison with her progress before the operation. Of the thirty-two patients whose mental recoveries were hastened by the operations twenty-five, or 78 per cent., were in cases in which the insanity showed the dominating symptom of depression. In the old classification existing in the hospital prior to 1904, these were grouped under melancholia, acute and chronic; involution melancholia, and depressive hallucinosis. In the new classification now adopted the majority of such conditions are placed under one head, manic-depressive insanity, and others to the involution period of life. Five of the remainder, or 15 per cent., were patients in an excited or exalted mental state. The remaining two patients were with a diagnosis of dementia præcox and paranoic symptoms. Fifty-eight per cent. of the number of patients who received hospital treatment and operations within six months after the commencement of their insanity were improved or recovered; thirty-three per cent. of those receiving treatment and operations within a year improved or recovered; these did not include the cases in the first class; twenty-six per cent. of those receiving treatment and operations after the expiration of a year were improved or recovered. The number of recoveries taking place among those with whom treatment was commenced within six months after the commencement of the mental disturbances was five times as great as among those in whom treatment was commenced at a later date. Forty-four per cent. of the 72 were discharged as recovered or had their improvement hastened by the operations performed. Why it was that some recovered and others with a like mental disturbance, even under the most advanced treatment, failed to respond, could only be answered by citing a parallel with physical diseases. The ability to improve varied with each individual, whether mental or physical.

Intrapelvic (Subpubic) Versus Abdominal Method of Dealing with Mechanical Obstruction to Delivery.—Dr. Richard C. Norris of Philadelphia said that the modern results of elective section justified the extension of the limit of the absolute indication. He pointed out what this limit should be and spoke of the degrees of relative disproportion which existed and which furnished debatable ground. Reference was made to the factors to be studied before or during labor that promised spontaneous delivery or safe operative assistance. The actual test of labor should not be abandoned. He spoke of the methods and value of fetometry, of pelvimetry, and of studies to determine the character of the membranes, of the cervix, and uterine energy. The status and methods of induction of premature labor or minor degrees of relative disproportion were described and personal statistics given. He spoke of the value and limitations of forceps and version. He referred to the circumstances which justified section of the pubic bone. Pubiotomy was preferable to symphyseotomy. The accidents of pubiotomy were best avoided by the most approved technique and by skilled operative delivery, which included complete preliminary dilatation of the birth canal.

(To be continued.)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

State Medical Examining Board of Washington.

Spokane, January 7, 8 and 9, 1908.

NERVOUS DISEASES AND DISEASES OF EYE AND EAR.

1. Name three diseases in which tremor is a prominent symptom.
2. Describe migraine.
3. Name the symptoms that may exist in the preataxic stage of locomotor ataxia.
4. Give the difference in the late condition of the muscles in cerebral palsy of infancy and infantile palsy.
5. Name three diseases in which the condition of the eyes may assist in diagnosing, and detail each.
6. (*a*) Name the symptoms of mastoid disease. (*b*) Name the most serious complication of mastoid disease.
7. In what disease may acute otitis media occur as a complication?
8. What are the symptoms of iritis? What are its most frequent causes?
9. What is strabismus? What muscles are involved? In a child what is the appropriate treatment?
10. What are the dangers to the eye in a corneal ulceration?

PREVENTIVE MEDICINE AND MEDICAL JURISPRUDENCE.

1. Give the legal definition of insanity.
2. Define malpractice, civil and criminal.
3. What is rigor mortis? What is the significance of its instantaneous onset?
4. Under what circumstances would you report a case to the coroner for investigation?
5. Differentiate wounds made before and after death.
6. Describe the prophylaxis against amebic dysentery.
7. What prophylaxis should be adopted during an epidemic of diphtheria?
8. What diseases may be conveyed by the eating of pork?
9. Describe an efficient quarantine against smallpox.
10. Give the period of incubation and the duration of the infection after the subsidence of the acute symptoms in scarlet fever, measles, diphtheria, and smallpox.

ANATOMY AND PHYSIOLOGY.

1. Locate the principal groups of lymphatic glands.
2. Name five muscles of the shoulder and arm. Give the origin, insertion, and action of any two of the five.
3. Describe Poupart's ligament, naming its anatomical formation, relations, and uses as a surgical guide.
4. Name the branches of the abdominal aorta.
5. Name the ganglia connected with the fifth pair of cranial nerves.
6. Briefly describe the bones of the foot, giving their divisions and articulations.
7. Name the structures that maintain the bladder in position in the male and female.
8. Describe the triangle of the elbow and name the structures that pass through it.
9. What are the functions of the brain membranes?
10. What office does the Eustachian tube perform?
11. Describe the white blood corpuscles, giving their source, composition, and properties.
12. What changes take place in the composition of blood as it passes through the kidneys?
13. What is the function of the anterior spinal nerve roots and how is it proven?

14. Define and describe (*a*) respiratory rhythm, (*b*) respiratory sounds.
15. Describe the factors which cause the heart sounds.

OBSTETRICS AND GYNECOLOGY.

1. Describe the normal expelling forces in labor.
2. Give the management of a shoulder presentation.
3. What circumstances necessitate the introduction of the hand or fingers into the uterus during or after delivery?
4. Give your method of preserving the perineum during the second stage of labor.
5. Name the indications for terminating a pregnancy at the end of the seventh month.
6. Give the causes and symptoms of cystocele.
7. Give the treatment of vaginismus.
8. Give the symptoms and treatment of pyosalpinx.
9. Give the complications which may occur with ovarian cysts.
10. Give the treatment of gonorrheal endometritis.

CHEMISTRY AND TOXICOLOGY.

1. Give the formula, properties, and preparation of each of two of the following: potassium iodide; hydrochloric acid; potassium chlorate.
2. Give three tests for recognizing the presence of sugar in urine.
3. What inorganic salts enter into the formation of human bone?
4. What is formaldehyde? How is it prepared?
5. How would you test for hydrochloric acid in the gastric juice? Give the test for lactic acid.
6. Name the symptoms of iodoform poisoning. What disease may it resemble?
7. How would you detect the presence of one of the following in food products: boric acid; formalin; salicylic acid?
8. Name three drugs to which the following are antidotes; tannic acid; lime; albumin.
9. Give the treatment of poisoning by illuminating gas.
10. Give the symptoms and treatment of cocaine poisoning.

SURGERY.

1. Describe senile gangrene. When would you amputate?
2. Give the symptoms and treatment of vesical calculus. How would you differentiate it from renal calculus?
3. Describe all the dislocations of the ankle joint that may occur.
4. Give in detail two methods of skin-grafting.
5. How would you treat a compound fracture of the lower third of tibia and fibula?
6. Differentiate hydrocele from irreducible scrotal hernia.
7. Give the characteristic symptoms of the three stages of syphilis. When would you begin treatment?
8. Give the symptoms and treatment of shock following injuries. When would you and when would you not operate?
9. Describe an operation for (*a*) tracheotomy; (*b*) for intubation. When is the former to be preferred?
10. Give your method of repairing an incised transverse wound of the palmar surface of wrist extending to the bones.

MATERIA MEDICA AND THERAPEUTICS.

1. Under what conditions would you prescribe (*a*) ergot; (*b*) bromide of potassium; (*c*) hyoscyamus?
2. Name five sedatives and give the indications for the use of each.
3. Name four methods of introducing medicine into the system and give the relative dose by each method.
4. Give the classification, properties, dose, physiological action and therapeutic uses of belladonna and strychnine.
5. Give the derivation of and the therapeutic use of (*a*) ichthyol; (*b*) iodine.
6. Name five agents that are germicidal in their action.
7. What are the indications for cold as a therapeutic agent? How does it produce its effect?
8. When would you use the following drugs (*a*) arsenious acid; (*b*) tincture aconite; (*c*) salicylate of soda; (*d*) acetanilid?
9. Name five vegetable and three mineral astringents describing the method of administration and the dosage of each.
10. Write a prescription for a child suffering from pertussis.

HISTOLOGY, PATHOLOGY, AND BACTERIOLOGY.

1. Describe in general the morphology of bacteria; grouping; mode of multiplication; spore formation.
2. Name five important culture media and one important bacterium that thrives best upon each.
3. With what three organisms may the bacilli of tuberculosis be confounded? State the order of procedure and differentiate between them.
4. What is bone marrow? How many kinds are there? What histological elements enter into its composition?
5. How many kinds of tissue are there? Name them.
6. Is epithelium necessarily derived from preexisting epithelium?
7. How many kinds of thrombus are there? Name causes of, character of, and the later changes that occur in them.
8. Pathologically, what distinguishes tubercular from other forms of pneumonic consolidation?
9. State the morbid processes that may result from arrested nutrition, impaired nutrition, and increased nutrition.
10. Give the bacteriology and pathology of bubonic plague.

PRACTICE OF MEDICINE AND DISEASES OF CHILDREN.

1. Enumerate the points of diagnostic value in interstitial nephritis. Name the associated conditions.
2. In what condition may we have hemoptysis? Explain the importance of the symptoms as to prognosis and diagnosis.
3. Differentiate endocarditis and pericarditis.
4. Give the etiology and symptoms of acute articular rheumatism. With what disease may it be confounded? On what points would a differential diagnosis depend?
5. Differentiate between chronic gastric ulcer and cancer of the stomach.
6. Give the physical signs of two stages of tuberculosis of the lungs.
7. Define (*a*) Hodgkin's disease; (*b*) Addison's disease.
8. Describe gastric vomiting; cerebral vomiting; Cheyne-Stokes respiration; colliquative diarrhea; a dicrotic pulse; a trip-hammer pulse; Hippocratic countenance.
9. Wherein do you expect the symptoms in typhoid fever to differ in children (under ten years) as compared with adults?
10. Make a diagnosis of one form of congenital valvular heart lesion and give the prognosis.
11. Give the respiratory rate at birth; at one year; at two years; at six years, and at twelve years.
12. What is marasmus? Name its cause and treatment.
13. Name three of each group of the stigmata of degeneration (*a*) anatomical; (*b*) physiological; (*c*) psychical.
14. Name the causes of enuresis.
15. Describe the differences in the eruption of chickenpox and smallpox.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

STATE MEDICAL EXAMINING BOARD OF WASHINGTON.

Spokane, January 7, 8 and 9, 1908.

NERVOUS DISEASES AND DISEASES OF EYE AND EAR.

1. Three diseases in which tremor is a prominent symptom: Paralysis agitans, plumbism, and alcoholism.
3. The symptoms that may exist in the preataxic stage of locomotor ataxia are: Numbness in the feet, uncertainty in walking, weakness of sexual function, impairment of bladder control, lightning pains, loss or diminution of knee jerk, inability to stand with the feet together and the eyes closed.
4. In the *cerebral palsy of infancy* will be found: Contractures, rigidity, increase of the deep reflexes, and sometimes athetosis; in recent cases there is no atrophy.
In *infantile palsy* the contractures, rigidity, increased deep reflexes are absent; and there may be atrophy.
5. Three diseases in which the condition of the eyes may assist in diagnosing: Chronic interstitial nephritis, locomotor ataxia, and cerebellar tumors.
7. Acute otitis media may occur as a complication in scarlet fever.

PREVENTIVE MEDICINE AND MEDICAL JURISPRUDENCE.

1. Insanity is defined, in Allbutt's System of Medicine, as "such a disorder or disease of the nervous system as prevents the individual from reacting normally as a member of the society to which by birth and education he belongs."
2. *Malpractice* is a failure on the part of a medical practitioner to use such skill, care and judgment in the

treatment of a patient as the law requires; and thereby the patient suffers damage. If due to negligence only, it is *civil malpractice*. But if done deliberately, or wrongfully, or if gross carelessness or neglect have been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice*.

3. *Rigor mortis* is the condition of rigidity or contraction into which the muscles of the body pass after death. It begins at a period varying from about fifteen minutes to about six hours.

"Rigor mortis does not follow immediately upon death in any case; a shorter or longer period of complete muscular relaxation intervenes."—(Schultze, in *Reference Handbook of the Medical Sciences.*)

5. A wound inflicted during life is generally characterized by hemorrhage, coagulation of the blood, eversion of the edges and retraction of its sides. It may also be inferred that the wound was inflicted during life if any of the following are noticed: The presence of inflammation, swelling, pus, or gangrene on the edges of the wound, or if there is any sign of beginning cicatrization.

6. Prophylaxis against amebic dysentery would include: Boiling all water before use. No ice should be put *in* water or drink or food; thorough cooking of all food; the avoidance of raw vegetables and fruit; thorough disinfection of the bowel discharges of those suffering from the disease.

8. Diseases which may be conveyed by the eating of pork: Tape worm, trichiniasis, tuberculosis, diarrhea, ptomaine poisoning, gastritis, enteritis.

ANATOMY AND PHYSIOLOGY.

8. *The triangle of the elbow* is situated at the upper part of the anterior surface of the forearm. It is *bounded*: *Above* by a line connecting the two condyles of the humerus; *externally*, by the Supinator longus; *internally*, by the Pronator radii teres; its *floor* is formed by the Brachialis anticus and Supinator brevis. *The structures that pass through it* are: The brachial artery and veins, the radial and ulnar arteries, the median and musculospiral nerves, and the tendon of the Biceps.

9. The *function of the dura* is protection: It forms the internal periosteum of the skull, it forms three partitions for the support of the parts of the brain, it forms sinuses or venous channels for the return of the blood from the brain, and it forms sheaths for the nerves as they leave the skull. The function of the *arachnoid* is lymph supply; of the *pia*, blood supply and nutrition.

10. The *function of the Eustachian tube*, is to keep the atmospheric pressure within the tympanic cavity the same as that on the outside.

11. The *white blood cells* are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes, (2) large mononuclear (3) transitional, (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their fate is uncertain; it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells. Their functions are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

12. As the blood passes through the kidney it loses water, salts, urea, carbon dioxide and extractives.

13. The *anterior* roots of the spinal nerves are efferent and motor and secretory and cause contraction of the muscles to which the nerves are distributed, or secretion in the glands to which the nerves are distributed.

The *proofs* of this are as follows: 1. *Division* of the anterior roots is followed by (1) loss of muscle movement; (2) dilatation and loss of tonus of the blood-vessels; (3) cessation of secretions from the glands; (4) impairment of the visceral muscles. 2. *Stimulation* of the anterior roots is followed by: (1) Tetanic contraction of the muscles; (2) changes in the caliber of the blood-vessels; (3) production of secretions from the glands; (4) variations in the tonus of certain visceral muscles.

15. The causes producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

OBSTETRICS AND GYNECOLOGY.

1. The normal expelling forces in labor, are: (1) The contractions of the uterus (which are the main factors, and are involuntary); (2) the contractions of the diaphragm and abdominal muscles.

6. CYSTOCELE: *Causes:* Lacerated perineum, prolapsed uterus, relaxation of the structures forming the pelvic floor, and subinvolution of the vagina after labor.

Symptoms: A dragging sensation in the lower pelvic cavity; a feeling of distention at the vulva; loss of power in urination; tumor of anterior vaginal wall, more apparent on straining.

7. The *treatment of vaginismus* consists in removing the cause when possible, tonics and general constitutional treatment, dilatation of the vaginal orifice; local application of a 5 per cent. solution of cocaine will relieve the hyperesthesia and allow of coitus. The condition is sometimes incurable.

9. The complications which may occur with ovarian cysts are: Inflammation, hemorrhage, suppuration, twisting of the pedicle, rupture, the formation of adhesions.

CHEMISTRY AND TOXICOLOGY.

1. POTASSIUM IODIDE. *Formula* KI.

Properties: Solid, white, odorless, tastes salty and sharp, fusible, volatile, very soluble in water.

Preparation: $6KHO + 3I_2 = KIO_3 + 3H_2O + 5KI$.

POTASSIUM CHLORATE. *Formula:* $KClO_3$.

Properties: Solid, colorless, transparent, odorless, tastes cool and salty, moderately soluble in water, decomposes on being heated.

Preparation: $6KHO + 3Cl_2 = 5KCl + 3H_2O + KClO_3$.

2. *Three tests for recognizing the presence of sugar in urine:* The urine should first be tested for albumin. If this be present, it should be removed by heating the urine to near the boiling point, and filtering from the coagulum.

(1.) *Fehling's test:* Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of traces of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and Solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

(2.) *Fermentation test:* Three Smith's fermentation tubes are used, each containing a little compressed yeast, one filled with the liquid to be tested, the second with pure water, and the third with a dilute solution of glucose, and the three are put in a warm place over night. If gas collects in the first and third tubes, but not in the second, the liquid contains sugar; if gas collects in the third only it does not; under any other circumstances the yeast is at fault.

(3.) *Boettger's test:* Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test-tubes. To one test-tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color. (From Witthaus' *Essentials of Chemistry.*)

3. *The inorganic salts in human bone* are: Phosphate, carbonate and fluoride of calcium; chloride of sodium; phosphate of magnesium.

4. Formaldehyde is methyl aldehyde H.CHO.

It is *prepared* by the dry distillation of calcium formate:

$$Ca(H.COO)_2 = CaCO_3 + H.CHO.$$

5. *Test for free hydrochloric acid in the gastric juice:* The best is probably the Dimethylamido-azobenzol test; the reagent is used in 0.5 per cent. alcoholic solution, of which one or two drops are added to a like amount of the filtered gastric juice. If free HCl is present, the yellow solution turns red.

"The presence of lactic acid is detected by *Uffelmann's reagent*, which consists of a solution of Fe_2Cl_6 and phenol, diluted to an amethyst-blue color, which is changed to yellow by lactic acid. In order to avoid error by the action of other substances which have a like action upon

the reagent, 10 c.c. of the filtered gastric contents are agitated with ether, and the ethereal extract separated and agitated with the reagent; or it may be evaporated, the residue dissolved in water, and the solution added to the reagent."—(Witthaus' *Manual of Chemistry.*)

6. *The symptoms of iodoform poisoning*, are: (1) An erythematous rash, or eczematous eruption; (2) high temperature, small and rapid pulse, faintness, headache, mental depression, delirium, thirst, nausea, gastrointestinal disturbances; or (3) mental confusion, dizziness, cardiac depression, prostration, and coma.

7. *To detect the presence of boric acid in food products:* "The substance is rendered alkaline with milk of lime, evaporated to dryness, and incinerated. The ash is dissolved in the smallest possible quantity of concentrated hydrochloric acid, separated from carbonaceous matter by filtration, and the filtrate is evaporated to dryness on the water-bath. An appreciable loss of boric acid is not to be apprehended. The mass is then moistened with hydrochloric acid, slightly diluted, saturated with tincture of turmeric, and evaporated to dryness in the water-bath. In presence of the slightest trace of boric acid the dry residue appears of a scarlet or cherry color."—(Lehmann's *Practical Hygiene.*)

8. Tannic acid is an *antidote* to the alkaloids in general; lime to oxalic acid; albumin to corrosive sublimate.

9. *The treatment of poisoning by illuminating gas* consists in supplying fresh air or oxygen and in maintaining respiration. Cold affusions to the head while the body is kept warm, inhalation of ammonia, and transfusion of blood have also been recommended.

10. In *cocaine poisoning* there will be found pain and fullness in the head, pulse first quick, later feeble and slow, extremities cold. The symptoms are not constant.

Treatment consists in the administration of ammonia or coffee; morphine, strychnine, chloroform, and ether have all been suggested. The safest plan is to treat whatever symptoms are present.

The *antidote* is said to be amyl nitrite.

SURGERY.

2. *The symptoms of vesical calculus* are: Increased frequency of micturition; pain at end of urination, chiefly felt at the end of the penis or in the neck of the bladder; the urine may contain pus, mucus or blood; a "click" can be obtained by using a searcher or sound; examination by the cystoscope may reveal the presence of the stone.

The *treatment* consists in removing the calculus, by litholapaxy, or lithotrity, or lithotomy (suprapubic or perineal).

In *renal calculus* the pain may be in the loin, groin, or testicle; there may be no urinary changes; a "searcher" will not find a stone; cystoscopic examination is useless; but the *x*-rays may diagnose the calculus.

6. *Hydrocele:* Is pyriform in shape; the swelling is first noted at the lowest part of the scrotum; it is tense, smooth, and fluctuates; it is dull on percussion; it is *translucent;* the testicle is behind the tumor; there is no impulse on coughing.

Irreducible scrotal hernia: Is sausage-shaped; the swelling begins above; it is *not translucent;* the testicle is below the tumor; there is an impulse on coughing, as a rule.

7. *The first stage of syphilis*, is characterized by the *hard chancre.* The *second stage*, by: Sore throat, mucous patches; the skin lesions or syphilides, which are characterized: By not itching; by being of a coppery or raw ham color; by being painless; by polymorphism, macules, papules, pustules, etc., being present at the same time; by being generally symmetrical. In this stage may also appear: Iritis, periostitis, and alopecia.

The *third stage* is marked by: Anemia, gumma formation, periosteal nodes, headaches, endarteritis and various other diseases.

Treatment should be commenced as soon as the diagnosis is absolute; generally this is on the appearance of the secondary symptoms.

HISTOLOGY, PATHOLOGY, AND BACTERIOLOGY.

2.

FIVE CULTURE MEDIA.	ONE B. THRIVING WELL ON IT.
1. Gelatin.	Anthrax bacillus.
2. Agar.	B. of typhoid.
3. Potato.	Glanders B.
4. Blood-serum.	Tubercle B.
5. Hydrocele fluid (and agar).	Micrococcus of gonorrhea.

3. The bacteria liable to be mistaken for the tubercle bacillus are: the bacillus of leprosy, the bacillus of the smegma, and Lustgarten's bacillus. "The differential diagnosis between these four organisms depends upon the following reactions: When stained by the carbol-fuchsin method, commonly employed in staining the tubercle bacillus, the Lustgarten's bacillus becomes almost instantly decolorized by treatment with mineral acids, particularly sulphuric acid; whereas the smegma bacillus resists such treatment for a much longer time, and the lepra and tubercle bacillus for a still longer time. On the other hand, if decolorization is practised with alcohol instead of acids, the smegma bacillus is the first to lose color. The bacillus tuberculosis and the bacillus of leprosy are both very retentive of their color, even after treatment with acids and alcohol. If, then, we treat the preparation, stained with carbol-fuchsin, with sulphuric acid, Lustgarten's bacillus becomes almost at once decolorized. If it is not immediately decolorized, heat with alcohol; if it is then decoloried, it is the smegma bacillus. If it is still not decolorized, it is either the leprosy or the tubercle bacillus." (From Park's *Pathogenic Bacteria.*)

9. From *arrested nutrition*, may result: Necrosis and gangrene.

From *impaired nutrition*, may result: Atrophy, pulmonary emphysema, infiltrations, degenerations, and pigmentation.

From *increased nutrition*, may result: Hypertrophy and regeneration.

PRACTICE OF MEDICINE AND DISEASES OF CHILDREN.

3. In *endocarditis:* The sounds are in some relation to systole and diastole; are not superficial; may be conducted upwards or to the apex; are usually of a blowing character, or musical.

In *pericarditis:* The sounds are in no relation to systole and diastole; are more superficial; are not conducted upwards to the apex, though they may be heard over a wide area; are almost always of a friction or rubbing character, and are not musical.

4. ACUTE ARTICULAR RHEUMATISM. *Etiology* is not settled; it is supposed to be due to bacteria, but this is not yet proved.

Symptoms: Rheumatic pains in one of the larger joints (wrists, knees, elbows, ankles), which spreads rapidly to other joints. These joints are hot, red, swollen, and very painful; frequently the inflammation leaves one joint and appears in another. The body temperature may be very high; the pulse is rapid, soft, and full; the tongue is large and furred; profuse acid sweating is common; the urine is scanty and high colored, and may be loaded with urates. Anemia develops. Cardiac murmurs, either hemic or organic, may often be heard.

It may be confounded with *septic arthritis.* This latter would show evidence of a prior septic disease, a great tendency to pus formation, great variations in body temperature, the involved joints are more liable to be destroyed; the joint symptoms do not shift from one articulation to another, and the patient is usually more prostrated in septic arthritis.

5. *Gastric ulcer* is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl; there is no epigastric tumor, though the stomach walls may be somewhat thickened.

Cancer of stomach does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; there is progressive emaciation; severe anemia and cachexia are also present.

7. (*a*) *Hodgkin's disease* is a condition characterized by progressive enlargement of the lymphatic glands, with anemia, and secondary lymphoid growths in various other organs (spleen, liver, etc.).

(*b*) *Addison's disease* is a rare condition characterized by some pathological condition of the suprarenal glands and the sympathetic nervous system, and in which the skin becomes bronzed.

8. *Gastric vomiting* relieves the previous nausea, and returns on ingestion of food; salivation is present, also tenderness over liver and stomach.

Cerebral vomiting is projectile in character, and is accompanied by little or no nausea, is continuous even after stomach is emptied; there is no salivation, no tenderness over liver or stomach.

In *Cheyne-Stokes respiration* the respirations gradually increase in volume and rapidity until they reach a climax, when they gradually subside, and finally cease for from ten to forty seconds, when the same cycle begins again.

Colliquative diarrhea is a diarrhea attended with excessive discharges, and which causes much exhaustion of the patient.

Dicrotic pulse is a condition in which the first impulse as it strikes the examining finger is quickly followed by another impulse or secondary wave.

Triphammer pulse is characterized by a short, sharp impulse which promptly collapses.

Hippocratic countenance is characterized by: "A sharp nose, hollow eyes, collapsed temples; the ears cold, contracted, and their lobes turned out; the skin about the forehead being rough, distended, and parched; the color of the whole face being dark, livid, or lead-colored."

11. The respiratory rate (per minute) is: At birth, 45; at one year, 30; at two years, 25; at six years, 22; and at twelve years, 20.

13. STIGMATA OF DEGENERATION. (*a*) *Three anatomical:* Asymmetry of the skull, excessive prognathism, high, narrow arched palate.

(*b*) *Three physiological:* Nystagmus, defects in speech, l layed puberty.

(*c*) *Three psychological:* Excessive self-consciousness, morbid egotism, perversions of sexual instinct.

14. The *causes of enuresis* are: Phimosis, adherent prepuce, calculus, highly acid or alkaline urine, cystitis, intestinal worms, rectal polypi, fissure of the anus, hip-joint disease, spinal disease, general weakness of the nervous system, idiocy, and some of the infectious diseases.

15. *The eruption of chickenpox:* Usually appears first on the trunk, is evident on the first day, comes in successive crops, is not shotty, and disappears on stretching the skin; the spots are unilocular and collapse on puncture.

The eruption of smallpox: Usually appears first on the forehead and wrists, and on the third or fourth day; it is first macular, then papular, then vesicular, and finally pustular; it does not appear in successive crops; the spots are multilocular, and do not collapse on being punctured; the papule is hard and shotty, and does not disappear on stretching the skin.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.		
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan.	5
Arizona*	Ancil Martin, Phoenix	Phoenix	Oct.	5
Arkansas*	F. T. Murphy, Brinkley	Little Rock	Oct.	13
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	Los Angeles	Dec.	1
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	Oct.	6
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov.	10
Delaware	J. H. Wilson, Dover	Dover	Dec.	8
Dist. of Col'bia.	Geo. C. Ober, Washington	Washington	Oct.	13
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	Nov.	11
Georgia	E. R. Anthony, Griffin	Atlanta	Oct.	6
Idaho	W. F. Howard, Pocatello	Boise	Oct.	6
Illinois	J. A. Egan, Springfield	Chicago	Oct.	21
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis	Sept.	16

WOUNDS OF THE HEART, WITH A REPORT OF THREE CASES, AND CONCLUSIONS DRAWN.*

BY L. L. HILL, M.D.,

MONTGOMERY, ALA.

WOUNDS of the heart may be either non-penetrating or penetrating, injuring the cardiac wall, or opening a cavity. The left ventricle is most frequently injured, and the left auricle is least so. Auricular wounds are more fatal than ventricular ones, and injuries of the apex are less dangerous than either. A needle puncture will rarely cause hemorrhage from a ventricle, but excessive bleeding, which is mostly systolic, is liable to follow a like injury to an auricle. A wound inflicted during diastole is less dangerous than a similar injury during systole, perpendicular wounds are more fatal than diagonal, and those of the right heart bleed more profusely than those of the left. The presence of the foreign body in the heart, the size of the wound, the location of the wound, the number of wounds, the connecting cavities, the attending syncope, the involvement of Kroenecker's coordination center, and the degeneracy of the cardiac muscle are important factors in determining the outcome.

Pericarditis, myocarditis, endocarditis, cerebral embolism, and empyema are frequently secondary complications. When the wound heals spontaneously there is a possibility of cicatricial stretching, and subsequent rupture, as in a case reported by Izzo, of a man stabbed in the left ventricle, who was conveyed to the hospital, from which he was discharged as cured on the twenty-eighth day; a few hours afterward, while lifting a heavy body, he fell and quickly died. At the autopsy the cicatrix of the left ventricle was found ruptured. Loison has collected nine such cases. In addition to the injuries of the heart caused by bullets, daggers, knives, needles, and various implements of war, it may be wounded by a fractured rib, by a foreign body that has perforated the esophagus, or by blows upon the chest. Traumatic ruptures are more frequent after a full meal, as the distended stomach pushes the heart upward and forward, and causes a large area of the organ to be in contact with the thoracic wall, and receive the impact. Newton and Gamgee have collected forty-five cases in which traumatisms caused rupture of the heart without opening the pericardium. All were fatal. Only one of Gamgee's cases survived the injury fourteen hours. The fatality is easily understood, for there being no exit, as soon as the accumulation of blood exceeds the limit of pericardial distensibility the cardiac movements are mechanically stopped. The surgeon not only would be justified, but it is his bounden duty to operate upon every one of these cases, for it is more important, if possible, to rescue a drowning heart than to relieve a strangulated hernia. It is possible for a foreign body, as a gun missile, to remain quiescent for years in the myocardium, as in the case of a British officer, reported by Stevenson, who carried a bullet encapsulated for eleven years, or the still more remarkable case of Beers (Cincinnati *Lancet-Clinic*, 1898) of an American soldier who survived the lodgment of a bullet in the wall of the left ventricle for thirty-seven years.

Symptoms.—There is no certain cardinal sign by which an injury of the heart can be denoted, but when we consider the location of the external wound and, if large, the usually profuse hemorrhage from it, which may spurt, in connection with other signs and symptoms, it can generally be recognized. The *x*-ray furnishes valuable assistance, since it shows an enlargement of the cardiac outline and the presence of any foreign body, as in a case that I will subsequently report. In children the heart is an intercostal space higher than in adults. In the fourth, fifth, and sixth intercostal spaces near the left edge of the sternum the heart comes close to the surface and can be easily injured. The pulse is weak, irregular, intermittent, and often imperceptible in the extremities. There are pain, pallor, restlessness, and generally dyspnea. Frequent attacks of syncope are common. The mind is clear, but the countenance depicts an anxiety and distress that seemingly would welcome death, with the wintry sterility of the grave, as a sympathizing friend. If there is much blood in the pericardium the heart sounds are indistinct, and percussion elicits increased dullness. With the pulsation of the heart a foreign body, as a needle, may be seen to move under the skin—a symptom, centuries ago, enshrined in the magnificence of indestructible verse.

> "He fell, the spear point quivering in his heart,
> Which, with convulsive throbbing, shook the shaft."

Prognosis.—The chief dangers are shock, hemorrhage, and infection. Ninety per cent. are penetrating, and of these only 19 per cent. are instantly fatal. Of the seventy-five deaths in the operative cases, sixteen occurred on the operating table or within the first hour after the operation, and seventeen from seven hours up to two days, which makes a mortality of 44 per cent. from hemorrhage and collapse. Thirty died in consequence of infection, which is 40 per cent. Consequently 84 per cent. of the seventy-five patients died of hemorrhage and infection. In nearly all of the infective cases the patients died of purulent pericarditis or empyema. In twelve of these the pericardium was primarily closed. Of the one hundred and twenty-four cases of

*Read before the Alabama Medical Association, April 22, 1908.

heart suture recorded there were forty-nine recoveries, or about 40 per cent., as against 10 per cent. of recoveries without operation. One hundred and nine were stab wounds, with forty-three recoveries, or about 39 per cent., and fifteen gunshot wounds, with six recoveries, or about 40 per cent. Fifty-five times the left ventricle was penetrated, with twenty-five recoveries, or 45 per cent., and fifty times the right ventricle, with sixteen recoveries, or 32 per cent.

Perforations of the auricles are so infrequent that no reliable statistics have been gathered, but we are safe in assuming a much greater mortality. Contrary to the common belief, these statistics show a more frequent injury of the left ventricle than of the right. In the two cases in which the left coronary arteries were ligated death resulted from infection.

Treatment.—I presume no one will question the propriety of immediate operative interference, as experience teaches that about 40 per cent. of cases recovered in which the heart had been sutured as against 10 per cent. of recoveries in which no operation had been performed. According to Rehn there is not a single death attributable to surgical manipulation, and though sixteen patients have died upon the table, other causes were obvious. In the case of a girl sixteen years of age Podrez probed the left ventricle for a bullet, made ten insertions with a needle, and kneaded the organ with his entire hand, using considerable force, in a vain effort to locate the missile. During his search no interruption of the heart beat occurred and the girl recovered. A needle should be removed at once, but a knife blade or dagger must not be touched until the surgeon has bared the heart and is master of the situation, since an uncontrollable hemorrhage might occur, as in the case of the late Empress of Austria when a file was unfortunately prematurely extracted. It hardly seems necessary to accentuate the fact of the necessity of perfect asepsis in this operation, as forty per cent. of the deaths were due to infection. Diminished resistance from loss of blood and want of cleanliness from hurry of preparation are largely contributive causes. Until every aseptic precaution has been taken mechanical stoppage of the heart from blood in the pericardium should be prevented by aspirating. If the escape of blood in the pericardium is very rapid seven ounces may be sufficient to cause death, but if gradual a much larger quantity will be tolerated. Moullin reported a case in which "the pericardium contained six pints of thin dark fluid which was removed and patient recovered." The needle passed through a flame is rendered aseptic and made to enter the sixth left space close to the sternal margin, the thickness of the bone, about one-third of an inch, then behind the sternum for half an inch, to escape the pleura, and raising the handle push the needle downwards into the pericardial sac—traveling a little more than two inches. The operation has a mortality of a little the rise of one per cent. In case of unconsciousness with hardly a sign of life we should operate without an anesthetic, and upon the return of consciousness administer chloroform. No two operators have made similar external incisions for exposing the heart. Professor Rotter of Vienna performed a number of experiments upon the cadaver and concluded that the easiest way to expose the heart was by making an incision four inches in length along the lower border of the third rib, commencing three-fifths of an inch to the left of the sternum. A similar incision was made along the lower border of the fifth rib. The external ends of this incision were joined by a third. The fourth and fifth ribs were divided and the musculo-osseous flap was turned inward. If more space should be required the third could be included. If the incisions commenced four-fifths instead of three-fifths of an inch from the left sternal border we would certainly miss the internal mammary artery and would only be required to ligate the intercostals. This incision gives us an opportunity of removing any extravasation of blood and inspection of the pleural cavity with reference to other injuries. There are very few wounds of the heart without involvement of one of the pleura. If there is slight bleeding from the heart it may be controlled with a stitch, by pressure of the finger or by the introduction of a finger as Parrozzani did. Sometimes the bleeding is so profuse that suturing is impossible, but if the heart is pulled outward and turned to the right the bleeding will cease because the vessels are flattened and twisted. This harsh method causes great distress, but no death has been recorded from it. The operation can be made bloodless by compression of the right atrium. Professor Magnus of Heidelberg experimented upon dogs and demonstrated that a dog's heart would stand incomplete compression up to four minutes, and complete one and a half minutes, and Rehn thinks the human heart would be much more tolerant as it is not nearly so irritable as the dog's.

With the right hand gently lift the heart out of the pericardium and introduce from below the left hand, and immediately we feel the vena cava inferior, and its inosculation into the right atrium which should be pressed between the index and ring finger, and pushing upwards we displace the inosculation of the vena cava superior. Rehn truthfully remarks "we have in the compression of the right atrium venosum a means of bringing the most violent heart bleeding to a stop at once." In suturing be certain to get a good hold, do not include the endocardium, lest a brittle heart give way. I prefer the interrupted catgut stitch and to use an intestinal needle. Should the heart appear weary allow it to glide back into its normal position for a few moments. As few stitches as possible should be passed, commensurate with safety against leakage, as they cause a degeneration of the muscular fiber with its tendency to dilatation and rupture. Giordano, from his experiments upon rabbits, prefers Lembert's sutures in closing an auricular wound. The sutures should be passed and tied during diastole. Tubes are preferable to gauze for drainage as the latter is liable to cause a retention of the discharge and strangulation of the organ. Never close a pericardium with an open pleura because of the ease of infection in the latter which may extend to the pericardial wound and cause the formation of pus in the closed pericardium.

Case I.—This boy, Henry Myrick, whom I had the pleasure of showing you at the Talledega meeting five years ago, remains in excellent condition. He was at the time of the injury thirteen years of age and of rather delicate appearance. About six hours after the injury Dr. Parker was called, and, perceiving the nature of the case, advised that I should be sent for, and, upon my arrival, I urged an immediate operation. To this the parents readily consented, and I was assisted in the operation by Drs. Michel, R. S. Hill, Robinson, Parker, and Washington. The knife blade entered the fifth intercostal space, about a quarter of an inch to the right of the left nipple, and penetrating the apex of the heart, passed into the left ventricle. The wound was about three-eighths of an inch in length, and

from it came a stream of blood at every systole. There was no external bleeding, but his general condition was very unfavorable. The radial pulse was almost imperceptible and the heart sounds were heard with difficulty. There was a triangular-shaped area of dullness. He had dyspnea, and was very restless. His extremities were cold, as were his lips and nose. When aroused, he answered questions intelligently, though his countenance showed great distress. Securing two lamps I removed the boy from his bed to a table, at one o'clock at night, eight hours after the stabbing, and proceeded to cleanse the field of the operation, and place the patient in as favorable a condition as my surroundings in the negro cabin would allow. Commencing an incision about five-eighths of an inch from the left border of the sternum, I carried it along the third rib for four inches. A second incision was started at the same distance from the sternum and carried along the sixth rib for four inches. A vertical incision along the anterior axillary line was made connecting them. The third, fourth, and fifth ribs were cut through with the pleura. The musculoosseous flap was raised, with the cartilages of the ribs acting as hinges. There was no blood in the pleural cavity, but the pericardium was enormously distended. I enlarged the opening in the pericardium to a distance of two and one-half inches and evacuated about ten ounces of blood. The pulse immediately improved, as was commented upon by Dr. L. D. Robinson, who so successfully and skillfully administered the chloroform. I had my brother, Dr. R. S. Hill, pass his hand into the pericardial sac, and bring the heart upward, and at the same time steady it sufficiently for me to pass a catgut suture through the center of the wound in the heart and control the hemorrhage. I cleansed the pericardial sac with a saline solution, and closed the opening in it with seven interrupted catgut sutures. The pleural cavity was also cleansed with a saline solution. The musculoosseous flap was brought down and stitched in position. The operation lasted forty-five minutes. The patient's pulse, on reaching his bed, was one hundred and forty-five and respiration fifty-six. I injected strychnine hypodermically, and employed hypodermoclysis and autotransfusion. The following morning, September 15, the boy's pulse was 130, and temperature 102°, and he was slightly delirious. On September 16 there was but slight change in the temperature and pulse, though the delirium was much worse. On September 17 he commenced to improve, and his recovery was uninterrupted. Rehn was able to collect only two other cases of delirium following heart suturing. I allowed the patient to sit up on the fifteenth day.

Case II.—A girl was brought to my home about eight o'clock at night. She had carried in her shirt waist a needle two and a half inches in length which she had driven into her heart by accidentally falling against a tree. Her countenance was anxious, pulse rapid and weak, and respiration somewhat labored. She had slight pain about her heart. Upon inspection I found that the foreign body had entered the fifth intercostal space on the left side, and with the pulsation of the heart the head of the needle could be seen to move under the skin. The case being one of unusual interest to me I summoned my friend, Dr. R. F. Michel, and my brother, Dr. R. S. Hill, and proceeded to operate by injecting ten drops of a four-per cent. solution of cocaine into the skin. I made an incision an inch in length down to the needle, and extracted it with a pair of dressing forceps. The wound was immediately closed, and the child sent to a relative's house, with instructions to the parent that they detain her in bed, and that she be kept quiet for ten days. She had no subsequent trouble.

Case III.—This man, Willie Williams, was brought to my office five days after an altercation in which a piece of hat pin three inches in length was broken off in the heart. It was localized with an *x*-ray. It entered the fifth intercostal space near the sternum. So long as he remained in a sitting posture his pulse was distinct but irregular. If, however, he attempted to lie down, his face showed great distress and the pulse became imperceptible. I reached the foreign body by a modified Rotter incision and went straight down on the pericardium, as it was not necessary to open the pleural cavity as I was sure from the *x*-ray examination there was no extravasation of blood nor pleural injury.

Conclusions.—From my own experience and a careful review of the cases reported I have drawn these conclusions:

1. That any operation which reduces the mortality of a given injury from 90 to 60 per cent. is entitled to a permanent place in surgery, and that every wound of the heart should be operated upon immediately.

2. Whenever the location of the external wound and the attending symptoms cause suspicion of a wound of the heart, it is the duty of the surgeon to determine the nature of the injury by an exploratory operation.

3. Unless the patient is unconscious, and corneal reflex abolished, as in Pagenstecher's case, an anesthetic should be given, and preferably chloroform. Struggling is liable to produce a detachment of a clot, and renew the hemorrhage, as occurred in Parlavecchio's patient.

4. Never probe the wound, as serious injury may be inflicted upon the myocardium.

5. Rotter's operation renders access to the heart extremely easy, gives an opportunity of removing any extravasation of blood, and inspection of the pleural cavity with reference to the injuries.

6. Steady the heart before attempting to suture it either by carrying the hand under the organ and lifting it up, or if the hole is large enough, introduce the little finger, as Parrozzani did, which will serve the double purpose of stopping the bleeding and facilitating the passage of the stitches.

7. When the hemorrhage is so profuse as to preclude the possibility of suturing, with the right hand gently lift the heart out of the pericardium and introduce from below the left hand and press between the index and ring finger the vena cava inferior and its inosculation into the right atrium, and pressing upwards displace the inosculation of the vena cava superior.

8. Professor Magnus of Heidelberg believes that the heart will stand complete compression for a minute and a half and incomplete for four minutes.

9. Catgut sutures should be used, as wounds of the heart heal in a remarkably short time. The sutures should be interrupted, introduced, and tied during diastole, not involve the endocardium, and as few as possible should be passed commensurate with safety against leakage, as they cause a degeneration of the muscular fiber with its tendency to dilatation and rupture.

10. In cleansing the pericardium, it should be sponged out and no fluid poured into the sac, as quickly produced tension may cause serious consequences to an already disabled heart.

11. Until every aseptic precaution has been taken the mechanical stoppage of the heart from accumulation of blood in the pericardium should be pre-

vented by aspiration, as diminished resistance from loss of blood and want of cleanliness from hurry of preparation are largely contributive causes to the forty per cent. of deaths from infection.

12. Rehn suggests closing the pleura and draining the pericardial sac, but never the reverse, because of the ease of infection of the pleura, which may extend to the pericardial wound and cause the formation of pus in the closed pericardium.

13. For drainage, tubes are preferable to gauze, as the latter is liable to cause retention of the discharge and may strangulate the heart.

14. A needle may be removed at once, but a knife blade must not be touched until the surgeon has bared the heart and is master of the situation, as an uncontrollable hemorrhage might occur from premature extraction.

21 South Perry Street.

OBSERVATIONS ON THE TREATMENT OF EXOPHTHALMIC GOITER.*

By ANDREW J. McCOSH, M.D.,

NEW YORK.

One of the most interesting questions of the day is the treatment of exophthalmic goiter. On the one hand, the cures and improvements due to serum treatment and on the other the claims made by the advocates of the operative treatment of this mysterious disease stand opposed to each other. Medical treatment, whether it be by means of drugs, rest cure, electricity, or psychic influences, will probably always continue to be primarily applicable to the great majority of patients suffering from Basedow's disease. The number of patients, however, who will or must resort to treatment by means of sera or operation is ever on the increase. This is especially true during the past three years. This would not be the case were not the results of purely medical treatment rather disappointing, and those of serum or operative treatment rather encouraging.

I have already employed the term mysterious in reference to the disease, for we must all acknowledge, I think, that we are really entirely ignorant as to its etiology and, to a lesser extent, perhaps, as to its pathology. None of the theories which have been advanced as to its causation will stand the test. As an illustration of this uncertainty, we have the dispute as to its proper classification. The neurologist, the metabolist, the internist each claims the disease as belonging to his specialty. The surgeons have not yet made any such claim, but as more and more cases are drifting into their hands, a similar claim on their part may some day be justified. W. H. Thomson,[1] in a valuable article, thus expresses this view: "The only deduction possible is that the complaint is due to a specific poison which goes wherever the blood goes, and which causes no more tissue changes, except indirectly on nutrition, than does opium or aconite. What the nature and origin of this poison is remains wholly unknown." Nearly 3,000 treatises have been published on this subject with but meager results as to the etiology of the disease. Probably the most prevalent theory is that Basedow's disease is caused by hypersecretion or perverted secretion of the thyroid gland. There are many arguments, however, against this theory. Until we learn more about the function and secretion of the thyroid gland we can scarcely judge what would constitute the amount or character of the normal thyroid secretion. There is definite knowledge on one point alone, which is that myxedema follows the diminution of its secretion, and that the gland extract has a beneficial effect on both myxedema and cretinism. In this connection it is a curious fact that old people do not seem to need the thyroid secretion. The gland undergoes marked atrophy after the age of fifty, and its complete removal in old people rarely results in any condition which resembles myxedema. This fact alone tends to weaken the argument that Basedow's disease is due to alteration in the thyroid gland. Elderly people suffer from the disease and occasionally die as a result of it. In many cases of this disease the thyroid gland has apparently been unchanged, and in regions where ordinary goiter is common the exophthalmic variety does not seem to be especially prevalent. R. L. Thompson[2] has never found that the so-called tetania parathyropriva accompanies the atrophy of the parathyroid bodies which occurs in primary infantile atrophy.

One of the strongest arguments advanced in favor of the theory of hyperthyroidism was the fatal result which in the past has occasionally followed the operation of thyroidectomy. This was supposed to be caused by the toxicity of the thyroid juice which was squeezed from the gland during its removal. A tremendously rapid pulse, high temperature, great mental excitement, and flushed face were the symptoms, which in these fatal cases developed a day or two after operation. It was a natural process to argue that it was a toxic state caused by absorption of thyroid secretion. Many of us are now very doubtful of the truthfulness of such a conclusion. These alarming symptoms seem to be simply an exaggeration of those of the disease, which are enhanced by the mental shock or blood changes due to the operation, or perhaps to the anesthetic, if one has been administered. Personally, I doubt very much if the absorption of the secretion of the gland produces any direct toxic influence in these fatal cases. In my last dozen operations I have taken no pains to prevent expression of the thyroid juice into the wound, and have freely cut and handled the gland without any resulting bad symptoms. I have been warned more than once by surgeons in my clinic of the danger of such apparent recklessness, and some day a sad experience may be my punishment.*

In recent years the parathyroid glands have rather suddenly jumped into prominence. The first accurate, and still one of the best, descriptions of these small bodies was given by Sandstrom in 1880. He was the first writer to consider them of importance. He looked upon them as embryonic rests of thyroid tissue. According to his or the embryonic theory, they were regarded as immature thyroids. This theory, however, does not fulfil all the necessary conditions, as it has been shown by Forsythe and others that parathyroids and embryonic thyroids do not possess the same histological features. Forsythe concludes: "While some observations suggest that the parathyroids can develop into thyroids, the contention that parathyroids are merely embryonic thyroid is not proved." At a later period the Frenchmen, Gley,[4] and the Italians, Vassale and Generali,[5] maintained that the removal of the parathyroid glands generally resulted in tetany.

*Read at the Clinical Society on May 22, 1908.

*Since the writing of this paper I have lost one patient from acute hyperthyroidism. The operation consisted in ligation of the two superior thyroid arteries. The gland itself was not injured in the slightest. There was little shock, but death followed in twenty-four hours.

which frequently terminated fatally. Kocher and von Eiselberg soon learned from their own operative experiences that there was probably truth in this contention. Many other surgeons have accepted this theory, and believe that almost invariably tetany is caused by the removal or destruction of several of these bodies, and that if all be removed the result will be fatal. A most serious and often fatal complication of many of the operations of thyroidectomy performed a quarter of a century ago was tetany. Many now believe that this symptom was due to the destruction or removal of the parathyroid bodies, rather than to the more or less complete removal of the thyroid. This "vitally essential theory" has not as yet, however, been satisfactorily proven. There have been many contradictory observations. These may be largely due to the practical impossibility of exact recognition by the naked eye of these rather elusive bodies. They are constant in neither location, number, nor size; they may be deeply buried in the thyroid or may be microscopic in size; they may be joined to lymphatic glands or to the thyroid residues. Tetany has also been reported as following mere ligation of the thyroid arteries. It is possible, however, that in these cases the parathyroid glands may have been deprived of their blood supply, though experiments seem to prove that they do not depend entirely for their blood on the thyroid arteries. It has been apparenty demonstrated, however, that each parathyroid has its own little artery, usually a branch of the inferior thyroid. In Forsythe's interesting article he advances an evolutionary theory, and arrives at the following conclusion: "The parathyroids are portions of the main thyroid gland which have assumed functional activity, but have not yet formed vesicles. Parathyroid tissue may develop into thyroid tissue and intermediate types occur. The secretion of the parathyroid gland is a colloid material indistinguishable from the thyroid colloid. The parathyroids, therefore, are glands essentially thyroidal in nature, possessing no peculiar function, but engaged in the active secretion of the same substance as the thyroid gland."

L. Vincent[6] also draws the following conclusions: "It cannot be truly said that either thyroids or parathyroids are essential for life, since it is frequently possible to remove either or both without causing death."

While my own personal experience may be of little value, yet it is of interest to note that in over 200 operations on the thyroid gland I have never seen a sign of tetany. In none of these operations have I paid the slightest attention to the parathyroid glands, and in two of those patients the thyroid gland has been apparently entirely removed, and in others but a small fragment has been left. In some of these operations I have seen bodies which have suggested parathyroids, but I have never been able satisfactorily to identify them.

In spite of such confusing observations and contradictory opinions, it must be granted that results derived from chemical investigations, experimental operations on animals, and clinical studies are accumulating which apparently prove that the parathyroid glands are bodies of some importance in the animal economy, and that under certain conditions at least their juice or secretion possesses certain inhibitory or toxic qualities, the exact nature or potency of which is still unsettled.

I am not qualified to speak of the results of the purely medical as distinguished from the serum treatment. We all know, however, that exophthalmic goiter is a disease which often suddenly appears and as suddenly disappears, the reason for either of which occurrences we know not. We know also that many and many a patient has been cured by drugs, by rest, and by hygienic and psychic treatment. It seems to me that at the present day all patients should be treated by purely medical means before a resort to either antitoxins or operations. This view is in accord with that of most medical internists, but there are other physicians who adopt a more radical view. L. F. Barker[7] expresses himself thus: "Though nearly all patients improve by rest, a diet which does not stimulate the thyroid (milk), sodium phosphate, and fortnightly *x*-ray exposures, and although occasionally a patient will get well, very many go backward again as soon as the treatment is discontinued. In the very early cases surgery is capable of curing nearly 100 per cent., even in the outspoken cases almost 75 per cent. can be cured by operations judiciously planned and skilfully performed. Internal medicine up to this time has been utterly unable to obtain results comparable with these." It may be that with our increasing favorable experiences of surgical procedures we may soon adopt this rational view, but I doubt if many in this audience will as yet subscribe to Dr. Barker's conclusions. It is not easy as yet to give a definite position to the virtues of the various sera which are being used. Lack of sufficient time for observation, and the personal enthusiasm of both patient and physician, prevent any final judgment as to the number of patients cured. Undoubtedly the most effectual of the sera are the antitoxin and cytotoxin of Beebe and Rogers. Both these gentlemen certainly deserve the thanks of the profession for their painstaking and brilliant work in this important field. It can certainly be stated that more than one patient has been rescued from imminent death, that many patients have been markedly benefited, and that probably a certain proportion have been radically cured by the employment of these cytotoxins and antitoxins.

Europe acknowledges, but America does not perhaps generally recognize, that the first deliberately planned operation for exophthalmic goiter was a thyroidectomy done by an American, Dr. Van der Veer, of Albany, in the year 1869. During the following quarter of a century the operation did not gain great popularity. Accidents and bad results were not infrequent, and the mortality was great—15 per cent., and over. The last dozen years have, however, effected a great change in this particular. Accidents, such as tetany, are of very rare occurrence, and the death rate has been steadily diminishing, until it is certainly now not more than 8 per cent. At first we did not know how much of the gland it was necessary to remove in order to effect a cure. We are now much wiser in this respect, and the favorable results of our operations depend very largely on this knowledge. We now know that we must remove the larger part of the gland. To a certain extent, each case is a rule unto itself. If we remove too much, myxedema may follow; if we remove too little, improvement and cure may not result. It is difficult in each case to tell exactly how much to remove. Of course, it is better to remove too little rather than too much, for a second operation to reinforce the first is always possible. In general terms, from 65 to 80 per cent. of the gland should be removed, and three of the arteries should be cut and tied. The extent of the extirpation is sometimes governed by the anatomical shape and size of the gland. In certain operations we would, perhaps, like to re-

move but 75 per cent. of the gland, but we are forced by surgical difficulties to remove a considerably greater amount. Landstrom, who has written one of the best works on this subject, gives in detail the results of operations performed by two of his Danish colleagues. With an operative mortality of 5.5 per cent., he estimates the final results in the cases which he has been able to trace for years after the various operations on the thyroid gland had been performed, as follows:

	Excision of Half of Thyroid Gland	Ligation of Three Arteries	Excision of half of Thyroid Gland, with Ligation of Superior Artery of Opposite Side
Cure.....	37.5 per cent.	50 per cent.	80 per cent.
Improved....	25 "	16.7 "	20 "
Unimproved..	37.5 "	33.3 "	.....

It will be thus seen that the results improve proportionately to the amount of gland tissue removed or destroyed. The contrast of 37.5 per cent. of cures where half a gland only has been removed as against 80 per cent. where an additional artery was tied, and thus another quarter of the gland put out of commission, is very striking. Extensive operations cannot always be performed at one sitting. Two or three operations are often needed in weak patients before we are entirely satisfied that sufficient gland tissue has been removed or deprived of its blood supply. Sometimes the first operation must be limited to the ligation of a single artery, the superior thyroid of one side. Then in a fortnight or so the opposite artery can be ligated. The patient in the meantime nearly always shows distinct improvement, and in another fortnight one of the inferior arteries can be ligated, or the greater part of the gland removed.

If a program such as this is followed, the necessity for a general anesthetic may be obviated. As a rule, however, I very much prefer the administration of a general anesthetic. In Switzerland, and perhaps in other Northern European countries, the operation can be generally performed under local anesthesia. In this country, however, it is seldom possible, and rarely advisable. In dealing with our more highly sensitive people the operative shock to the conscious patient has seemed to me more dangerous than that of a carefully administered anesthetic. In my goiter operations I have twice only omitted to employ general anesthesia, and I cannot say that I have seen, except, perhaps, in a single instance, any grave deleterious effects which could be attributed to the anesthetic. In simple goiter my mortality has been less than 1 per cent., and in exophthalmic goiter less than 4 per cent. In my last fifteen cases the postoperative condition has never been such as to give any special anxiety. There have been no alarming symptoms whatever. During the past year I have operated on eleven patients, and not one has been confined to bed for more than fourteen days. In one of my recent cases, a rather severe one, the patient was out of bed on the sixth day, and able to take a railroad journey to her home in a neighboring city on the tenth day after the operation.

My own operations number 23, performed on 22 patients. There has been one postoperative death. This occurred eleven years ago, at a time when our technique was less perfect than it is at the present day. The operation was the second on the same patient. At the time of the first operation she had been very ill for many months. Her postoperative recovery, however, was uneventful. About 50 per cent. of the gland was removed. Slow but steady improvement followed, and at the end of eighteen months she considered herself as almost restored to good health. Soon after, however, the symptoms of Basedow's disease began to return, and continued to increase rapidly in severity. Twenty-six months after the operation she returned to the hospital, asking for further operative treatment, she herself being satisfied that the first operation had given her comparatively good health for a period of eighteen months. She was kept under medical treatment for several weeks, but failed to improve, and in June, 1897, at her own request, a second operation was performed. Her pulse was then averaging 150, and she was in a highly nervous state. During the operation her heart acted rather badly, her pulse being 180, and faster. About 75 per cent. of the remaining gland tissue was removed. After her return to the ward her temperature began to rise, and climbed rapidly to 106° and 107° F. Her pulse continued between 160 and 180. The face became very much flushed, and she was exceedingly restless, with a wild, anxious expression. These unfavorable symptoms increased, and she died about thirty hours after the operation, with symptoms of acute hyperthyroidism. At the time we thought death was due to acute poisoning by the thyroid secretion squeezed into the connective tissue of the neck during the operation. I now believe that this reasoning was false and that death was due simply to an acute exacerbation of her disease.

Of the 21 patients who survived the operation I have been unable to trace 2. Of the 19 patients whose present condition is known, I can report 4 patients as apparently cured, at 12, 8, 7, and 4 years, respectively, after operation. Twelve patients have been operated on during the past year, and each one of these has been markedly improved. All have gained in weight, the least gain being 6 pounds and the greatest 30 pounds. There is not one of these who now has a pulse over 90. The exophthalmus in each one has diminished. The other symptoms have proportionately improved. It is too soon to make a final report on these 12 patients, but they certainly can be classed as 12 improvements. Of the 3 other cases, 2 report marked improvement, but acknowledge that at times when under excitement the heart jumps up to 100, and that they still suffer from nervousness. I find that in these 2 patients but 50 per cent. of the gland has been removed. There is but one patient, the operation having been performed five years ago, who has not been benefited. About 40 per cent. only of his gland had been removed. He is now meditating a second attempt at cure by means of another operation.

I have had no experience with the removal of the sympathetic ganglia for the cure of this disease, and I have never had the slightest confidence in this procedure. Its dangers are great and its results most disappointing. It has at the present day but few advocates.

THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.

By JOSEPH WALSH, M.D.,
PHILADELPHIA.
ASSISTANT MEDICAL DIRECTOR HENRY PHIPPS INSTITUTE.

THERE is no single pathognomonic symptom by which tuberculosis of the lungs may be recognized before the tubercle bacilli appear in the sputum; there are, however, associations of several symptoms which make the diagnosis practically certain. The idea of the present paper is not to give all the symptoms that occur in a case of tuberculosis, but to so emphasize the importance of the different early symptoms that a diagnosis may be made from the association of a very small number of them.

The history and the symptoms have been arranged in the following manner: I. History of exposure to contagion. II. Symptoms elicited by the history. III. General symptoms. IV. Local symptoms. Moreover, each of the last three have been divided into very important, important, and suggestive. Under "very important" have been included those symptoms which almost point to a diagnosis of tuberculosis by themselves; under "important," those symptoms which would lead us to suspect tuberculosis; under "suggestive," those symptoms which ought at least to attract our attention sufficiently to make us wish to exclude tuberculosis by examination.

I. *History of Exposure to Contagion.*

This is one of the most important factors in making a diagnosis of incipient tuberculosis. Given the circumstances, for instance, of a patient living with a consort with known tuberculosis, a diagnosis can be made on fewer physical signs than if no exposure is found.

The best accepted opinion at present is that any member of a family in which tuberculosis exists who shows general ill health without evident cause should be examined for tuberculosis. In the German dispensaries when one member of a family is found tuberculous all other members of the family are examined for tuberculosis.

To determine an exposure to contagion it is necessary to go into the family history, and if nothing is found, into the occupation or associations of the patient, and if exposure is still negative, into the history of the house in which he has been living. In studying the family history it is not sufficient to take the patient's first statement that his father died of old age or of an accident, without inquiring the age at the time of death or how long after the accident.

It matters not how little detail is gone into after a definite exposure is found, but to decide exposure as "not found" every statement of the patient must be questioned. The following examples are frequent: Patient said mother died of confinement. Question: "How long after confinement?" Answer: "Well, she never properly recovered from the confinement, but became weaker and weaker, lost flesh, and eventually died." Question: "Did she cough?" Answer: "Yes, she caught a bad cold and coughed for about a year before she died." Pregnancy and labor are extremely important factors in bringing out a latent tuberculosis, and deaths following confinement should therefore be carefully investigated.

"Of what did your brother die?" was asked once. "He was hit with a bat and killed," came the answer. "How long after the accident did he die?" "Six months." "Was he in bed all that time?" "No, he was hit in the chest and consumption developed," came the answer.

"My father and mother died of smallpox seven years ago," said a man of thirty. "Were they robust?" "No, my mother was very thin and always complaining; my father was strong and robust when married, but he, too, was delicate before he developed the last illness." Such a history is suspicious, to say the least.

If, after questioning every statement in the family history and having included uncles and aunts, no exposure is found, it is necessary to go into the occupation. Moreover, it is absurd again to stop at the first statement given. The following is an actual case and illustrates: Patient male, age thirty-five. "What is your occupation?" "Motorman on a street car." "How long have you been a motorman?" "Three months." "What did you do previously?" "Worked in a cigar factory." "How long?" "Twenty years." Such a story is by no means exceptional. It is to be remembered that the two occupations giving the highest morbidity from tuberculosis are printing and cigar-making.

It may in general be stated that an occupation continued for a long time and necessitating close confinement in a poorly ventilated room, especially with many others in the same room, as in the two occupations mentioned, or in a sweat-shop, is suspicious as regards exposure. In taking the occupation history it is well to inquire into every occupation back to the schoolday period.

The danger of contagion through the house was proven years ago by Flick, and histories pointing to the house as the cause are not uncommon. Cases similar to this are met with: Mrs. F., age twenty-seven, married, with one child. No family or occupation history pointing to exposure. Husband perfectly healthy and with good family history. The couple lived with her parents till three months after the first child was born and then moved to a house for themselves. The family living in the house previous to their occupancy had a son and daughter die of galloping consumption. About one and a half years after moving into the house the second child was born. The mother left her bed two weeks after confinement, and three weeks later returned to it with acute miliary tuberculosis.

The following answers are not infrequent among the poorer classes: "How long have you been in your present dwelling?" "Five months." "How long in the one previous to that?" "One year." "The one previous to that?" "Eighteen months." "The one previous to that?" "Five years." Such a story in itself arouses suspicion of a possible exposure since people moving so frequently can seldom fail to come in contact with the contagion.

II. *Symptoms Elicited by the History.*

(*a*) Very important. 1. Chronic Enlargement of Cervical Glands.—We have only four diseases which produce chronic enlargement of the cervical glands, lymphatic leukemia, Hodgkin's disease, syphilis, and tuberculosis. The first three are usually excluded without difficulty, and yet physicians fear to say decisively that enlarged cervical glands are tuberculous. Another fact which is commonly overlooked is that the individual must have been exposed to contagion in order to acquire the disease; therefore, close attention should be paid to symptoms pointing to tuberculosis in other members of the family, because it is likely that they were exposed at the same time.

2. Pleurisy.—It is only necessary to say that two-thirds of the serous and a larger number of the chronic or repeated pleurisies are tuberculous.

3. Hemoptysis.—From an anatomical standpoint it is conceivable that a lesion properly situated may

be no larger than, or in fact not so large as a pea, in order to produce either pleurisy or hemoptysis. In the case of the hemoptysis associated with small lesions without cavitation, the blood usually comes from a congestion surrounding the tuberculous focus and not from the tuberculous focus itself. The most common cause for this congestion is a "cold" produced by the pneumococcus. In these cases the blood may be slight in amount (blood-streaked sputum) or there may be one or more pretty good sized hemorrhages (one to several ounces of blood). In the case of either hemoptysis or pleurisy (apart from pleuropneumonia) it may be said tuberculosis should be taken for granted until another cause is proven.

4. Fistula in Ano.—Like pleurisy and hemoptysis, fistula in ano is in the majority of cases tuberculous. Its presence calls for examination for tuberculosis elsewhere; its presence in connection with pulmonary symptoms is diagnostic unless another cause is plain.

Moreover any of these symptoms in one member of a family should awaken the attention to other symptoms in other members. I know two families in which the husband has fistula in ano, the wife of one having had frequent pleurisies, the wife of the other having had a rather severe morning cough for ten years or more. Though both women were treated by different physicians, their condition, which was tuberculosis, remained unrecognized, because no examination of the chest was made. The physicians attributed the first woman's symptoms to the frequent bearing of children (she had seven); the second woman's to eating too much, the cough was a "stomach cough." In both cases there were not only the symptoms in the patient to attract attention to the chest, but the added symptom of non-traumatic fistula in ano in the consort.

(*b*) Important. 1. Protracted Cough.—Cough is a positive sign of irritation in the respiratory passages, and, as a rule, of irritation in the lungs. Lay people speak of a natural cough and physicians of a stomach and nervous cough. There is no such thing as a natural or a stomach cough, therefore such an explanation is ridiculous. A nervous cough is possible, though rare, and should, therefore, be the last explanation given. In cases of mild tuberculosis the process may advance slowly without subjective symptoms or with only the mildest subjective symptoms for twenty years or more. One of the most common symptoms of mild tuberculosis is a dry, irritative cough sometimes spoken of as "hacking" without expectoration.

The question of cough may be put thus: The most common chronic disease of our day is tuberculosis of the lungs, its most frequent symptom is cough, which may be limited to a slight dry hack, attributed by the patient to irritation at a definite spot far from the actual lesion (for instance, a definite spot in the throat); therefore, in any case of chronic cough tuberculosis of the lungs should be eliminated before anything else is considered.

Tubercle bacilli are found in the sputum only after softening has occurred, and this is practically always the result of mixed infection. Infiltration without mixed infection may progress till considerable involvement has taken place. On the other hand, however, softening with the expectoration of tubercle bacilli is sometimes seen when the lesion is so insignificant as to be undetected by physical signs. It is important that a careful examination of specially selected sputum be made in every case no matter how early the signs, yet a diagnosis must not be made dependent on a positive finding.

The pathologico-anatomical explanation of cough with expectoration not containing tubercle bacilli in a case of tuberculosis of the lungs needs only a moment's consideration to be plain. About a tuberculous focus in the lung even when it is closed (surrounded by new formed connective tissue), and closed lesions are the rule in the early stages, there is always a certain amount of congestion. In this hyperemic area which is not in itself tuberculous, there is necessarily increased secretion. This over-secretion is, as a rule, small, though it may be large in amount. As it comes forth from the mucous membrane it is pushed onward by the ciliated epithelium to the trachea or larynx where it gradually accumulates till capable of setting up sufficient irritation to expel it by cough.

Though cough is an important symptom of tuberculosis of the lungs, even advanced tuberculosis of the lungs may exist without it, especially in young people. It is only a short time since an autopsy at the Phipps Institute on a boy of eighteen showed advanced tuberculosis of both lungs with extensive cavitation though the patient never coughed or expectorated up to the time of death.

2. Inability to Take a Deep Breath Without Coughing.—This is but rarely complained of and is not very frequently noticed by the examiner. When complained of or noticed it is an important symptom.

3. Progressive Loss of Weight.—This is only suggestive of constitutional disturbance. When it occurs apart from an acute disease, while the patient is carrying out his usual avocation, a very definite cause must be found to account for it. In a person exposed to tuberculosis in his home or in his occupation an examination for tuberculosis is called for.

4. Gastric Disturbances.—After cough the most common subjective symptom in early or mild tuberculosis of the lungs is loss of appetite or indigestion. This one symptom, therefore, especially in young adults, should always call for a careful examination for tuberculosis, though standing alone it scarcely constitutes a symptom of tuberculosis.

5. Night Sweats.—It may seem ridiculous to some to include night sweats as a possible symptom in the early diagnosis of tuberculosis; it is quite as surprising, however, to those who examine many cases to find how early they do occasionally occur. They appear to be usually due to mixed infection. Their presence at least calls for the exclusion of tuberculosis.

(*c*) Suggestive. 1. Progressive Pallor of the Skin.—In advanced life (past the age of 40) this may be a symptom of many conditions, in the young adult there are but few chronic diseases to consider. In general the same might be said of this symptom as of progressive loss of weight.

III. *General Symptoms.*

(*a*) Very important. 1. Evident Habitus Phthisicus.—It is always surprising the number of patients who present themselves with tuberculosis of the lungs written all over them, yet who have reached an advanced stage with this symptom crying out to the family doctor for notice. A boy growing rapidly may be thin yet healthy, but after he has stopped growing he does not remain in this condition and especially does not become thinner without some definite reason. At such a stage his condition should be looked into because even if he has not tuberculosis the experience of all ages goes to show that he is making himself an ideal soil for contagion.

2. Increase in the Pulse-rate.—This constitutes

in the majority of cases the earliest sign of pulmonary tuberculosis, yet the minority of cases in which it is absent is not small. In other words, though its presence suggests the possibility of tuberculosis its absence does not prove the contrary. This increase in the pulse-rate need not be continuous, but may require mild excitement or light exercise to bring it out.

3. Fluctuation in Temperature.—Like fluctuations of the pulse, a daily rise of temperature is very significant, though in early or arrested cases it may be absent. On account of the fact that the diagnosis of the presence or absence of tuberculosis is frequently made on one examination, and that examination in the morning, it appears to me that too much stress has been laid on the elevation of the pulse and temperature. The presence of these symptoms on one examination means something, but their absence absolutely nothing. It is a mistake to limit one's self to one examination especially in a negative diagnosis of tuberculosis, and the only proper way of learning the temperature is by taking it at least several times a day for several days.

(*b*) Important. 1. Dyspnea.—There are four prominent causes for dyspnea, namely, disease of the lungs, heart, kidneys, and blood, and of these, disease of the lungs stands naturally first. It ought, therefore, be the first to be excluded. It must not be forgotten that dyspnea in these cases is due not alone to the amount of lung involved (because if it were, dyspnea would never be an early symptom) but to the combination of this with the action of the toxin on the heart, kidneys, and nervous system.

2. Hectic Flush.—Hectic flush in conjunction with another symptom, for instance exposure to contagion, is very significant, yet a hectic flush alone is not to be entirely ignored, and warrants an examination.

3. Clubbed Fingers or Curved Nails.—Clubbed fingers or curved nails are a symptom of many conditions in connection with the heart and lungs. Though they may be absent in even an advanced case of chronic pulmonary tuberculosis, they are sufficiently frequently present even in early chronic cases to demand that tuberculosis be sought for.

4. Bilateral and Especially Unilateral Dilatation of the Pupils.—Though we do not understand the reason for this symptom (it is supposed to be possibly due to pressure of enlarged bronchial glands on the sympathetic nerves) it is sufficiently common in connection with pulmonary tuberculosis to be considered a little more than suggestive.

(*c*) Suggestive. 1. Vague Neuralgic Pains.—These are most frequent and characteristic in one shoulder joint and in the muscles of the thorax, but may occur in any place in the body. The atrophy of and the pains in the muscles of the thorax are apparently due to coincident myositis, though many consider them reflex in origin. They are frequently limited to a spot near the intrathoracic lesion. Some even insist on a definite relation between the pulmonary lesion and the degree of muscular atrophy. The pains elsewhere in the body are apparently due to a toxin, either the toxin of the tuberculosis, or of a mixed infection, or to the antitoxin of the tuberculosis. This last is suggested on account of the frequency of severe rheumatism in arrested cases.

2. General Lack of Resistance.—General lack of resistance to disease as evidenced by susceptibility to other diseases especially typhoid fever.

3. Frequent Chilly Sensations.—Frequent chilly sensations or flushings of heat or what is frequently called "a touch of malaria."

4. Central or Peripheral Nervous Disturbances.—These are not uncommon manifestations of the toxemia. The number of the insane dying of tuberculosis has often been remarked. In the past it has been said that the insane were especially liable to tuberculosis; this opinion is changing and now tuberculosis is more frequently made the cause of the insanity.

5. Enlargement of the Thyroid Gland.—This is found so commonly in women that even its slight significance may be denied. Yet it is apparently more common in tuberculosis.

6. Herpes Zoster.—This seems to be more common in association with pulmonary tuberculosis than apart from it.

IV. *Local Symptoms.*

(*a*) Very important. 1. Change in Percussion Note with Prolonged Expiration.—This combination of symptoms brought out by percussion and auscultation always point to a local lesion. It is especially suspicious of tuberculosis when it occurs in situations of predilection as above or below the clavicles, in the supra or infra spinous fossæ or along a line corresponding to the upper margin of the lower lobe. This horizontal line extends around the chest just above the nipple. The region underneath the infraspinous fossæ is best reached by having the patient place the hand of that side on the opposite shoulder.

Chronic local lesions in the lungs are practically limited to the following diseases: Carcinoma, syphilis, glanders, actinomycosis, abscess, and tuberculosis. Carcinoma and syphilis are readily excluded and in the very great majority of cases do not enter into consideration. Glanders is confined to a special occupation and usually manifests distinct symptoms elsewhere. Actinomycosis is also limited to special occupations. Abscess is always a sequela of a process that can be recognized in the history. Excluding these five a local chronic lesion means tuberculosis.

2. Râles of Any Description Over Limited Areas Especially Those of Predilection.—Two especially common sites may be mentioned, above the clavicle and in the space between the scapulæ. Râles should be sought first during natural breathing, then during forced breathing, and finally after coughing. Like the combination of dullness with prolongation of expiration, râles over a small area point to a local lesion, and must, therefore, be given their proper weight in regard to tuberculosis. Râles widely distributed over one or both lungs usually indicate an acute bronchitis. It is to be remembered that acute bronchitis is much more common in persons affected with tuberculosis of the lungs than in others.

(*b*) Important. 1. An Unilateral Supraclavicular Depression on Inspiration.—This is usually characteristic of pleurisy at the apex.

2. Granular Breathing.—Granular breathing might be classed as one of the very important local symptoms of tuberculosis, but it is difficult to describe, requires experience to recognize, and hence is not in the hands of every general practitioner. Granular breathing shows the inspiration split up into innumerable particles. For instance if we represent ordinary inspiration by a continuous line, we might represent cogwheel breathing by a broken line, and granular breathing by a dotted line.

3. Suppressed or Muffled Breathing at the Apex.—According to Turban the common causes of this are pleuritic exudation and plugging of a large bronchus with secretion.

4. Altered Vocal Fremitus or Resonance.—Increase usually points to consolidation, diminution

to thickening of the pleura or pleural effusion.

5. Atrophy of Scapular Muscles.—When marked this is of considerably more importance than is usually attributed to it. In conjunction with a fossa above or below the corresponding clavicle it becomes very suspicious.

(*c*) Suggestive. 1. Deep Soreness on Percussion.—This soreness has always appeared to me to be in the muscles of the chest and has the same significance as the muscular pains in the chest.

2. Spinal Curvature or Droop of One Shoulder.—The frequent association of this with pulmonary disease has been remarked. Osler calls attention to the liability of subjects of spinal curvature to acute bronchitis; their liability to tuberculosis is even as marked.

3. A Lessened Expansion on One Side.—This is brought out by inspection and palpation. Osler says: "Place the hands in the subclavicular spaces and then in the lateral regions of the chest and ask the patient to draw slowly a full breath." There are also instruments for demonstrating the same. This and the two following signs are important if marked, but when slight are not sufficiently definite to the general practitioner.

4. A Lessened Excursion of the Diaphragm.—The study of this symptom requires time and a greater number of cases than falls to the lot of the average practitioner. It may be found in two ways: (*a*) According to Litten, watch the shadow on the thorax walls when the patient is lying down with the feet towards a good light. This method is very simple when the patient is thin. (*b*) By the fluoroscope.

5. Lessened Excursion of the Lung.—This may be found in two ways: (*a*) Grasp the base of the thorax on both sides, thumb in front on seventh ribs and fingers behind on twelfth ribs. The difference in the rise of the ribs on the two sides will be evident. (*b*) By percussion: have the patient bend over and mark off on both sides posteriorly the line of deep resonance on full inspiration and full expiration.

732 Pine Street.

ACUTE ANTERIOR POLIOMYELITIS—A PATHOLOGICAL STUDY OF THREE CASES.*

By WILLIAMS B. CADWALADER, M.D.,

PHILADELPHIA.

PATHOLOGIST TO THE PHILADELPHIA ORTHOPEDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES.

Although acute anterior poliomyelitis had been recognized as early as 1784 by Underwood,[1] and by Badham[2] in 1835, it was not until Heine[3] in 1840 published his observations that it became established as a definite clinical entity. For many years the pathological anatomy remained obscure, but in 1860 Heine[4] and also Duchenne,[5] on purely clinical evidence, strongly urged the spinal origin of this disease.

Cornil[6] in 1863 was the first to demonstrate distinct lesions in the spinal cord. Prevost[7] in 1865 studied the spinal cord of a long standing case and found lesions confined to the anterior horns of the gray matter, with changes in the ganglion cells, and believed that the disease depended upon an acute primary change of the ganglion cells. This was confirmed three years later by Lockhart Clarke.[8] In 1868 Meyer[9] first pointed out that acute poliomyelitis also occurred in adults. Charcot and Joffroy[10] in 1870 upheld the view of Prevost as to the origin of the disease, but up to this time most observations had been made upon cases which died long after all the acute signs had disappeared.

Roger and Damaschino[11] in 1871 described the pathological changes found in the spinal cord of three children dying at intervals of two months, six months, and thirteen months, respectively, after the onset of the paralysis. They found perivascular round cell infiltration, small areas of necrosis, and degeneration and destruction of the ganglion cells, together with slighter changes in the white columns, and concluded that it was due to an acute inflammatory condition, particularly involving the anterior horns.

Archambault and Damaschino[12] in 1883 published a report of an acute case which was fatal in twenty-six days after the onset. This seems to have been the first acute case with necropsy on record. They found an acute myelitis of the anterior horns.

The first case which I wish to describe occurred in a child aged two years and seven months who was admitted to the Orthopedic Hospital and Infirmary for Nervous Diseases and died on the seventh day after the onset of the paralysis. The second and third cases occurred in adults dying on the fifth and fourth days, respectively, after the first signs of motor disturbance.

I wish to express my thanks to Dr. Crispin and Dr. Donhauser of the Pennsylvania Hospital for the pathological material of the second and third cases, and also to Dr. Spiller for many valuable suggestions in carrying out this study.

Case I.—White male, two years seven months. Family history negative. Was admitted to the Orthopedic Hospital and Infirmary for Nervous Diseases in Dr. Mitchell's ward under the care of Dr. Eshner, complaining of fever, pain in back, rigidity of the neck, headache, and weakness of both legs and arms; this condition had lasted two days.

Physical Examination.—Respirations were shallow and rapid; temperature 99 2-5. On respiration there was a violent upward movement of the larynx. Pupils were equal and reacted to light and accommodation. The thoracic and abdominal organs were normal. There was a total flaccid paralysis of both lower extremities. The tendon reflexes were absent, and there was a flexor response on irritation of the soles of the feet. There was no atrophy of any of the muscles. The upper extremities were both somewhat weak. Sensation was normal everywhere. There was moderate rigidity of the posterior muscles of the back. Patient was very drowsy and weak. During the next five days the temperature varied from 99 to 101 and the patient was gradually growing weaker. Finally the respirations became shallow and rapid and patient died of respiratory failure on the seventh day of the disease.

The *autopsy* was performed the same day by Dr. Hill, the resident physician. Nothing abnormal was found in any of the abdominal or thoracic organs, excepting for intense general congestion. No cultures were made.

Brain.—The Vessels of the pia were much injected; otherwise no gross change was found.

Spinal Cord.—The dura was somewhat discolored about the cervical swelling, but there was no definite change which could be seen with the naked eye. On cross-section before the tissue had been put in formalin there could be seen numerous minute red dots and lines in the gray matter; some of these seemed to extend into the white matter as well. This was most marked in the lumbar swelling.

*From the Laboratory of Neuropathology of the University of Pennsylvania.

Sometimes the hemorrhages appeared to be more marked on the left side in the lumbar and sacral regions, and again higher up more marked on the right side. This appearance extended from the sacral region all the way up the cord through the medulla and pons, but gradually diminished in intensity from below upward.

Microscopical Examination.—Lumbar enlargement. There is a cellular infiltration which involves chiefly the anterior horns of the gray matter, but the intermediate portions and posterior horns are also affected to a less degree. The blood-vessels are dilated and engorged with blood corpuscles. In a few sections small areas of necrosis are found. The infiltrating cells are diffusely scattered, but here and there show a tendency to accumulate in the perivascular spaces. Many of the cells are of the lymphocyte type, having a small, round, deeply stained nucleus and a small amount of homogeneous, nongranular protoplasm, while others present a larger oval, indented and irregular nucleus less well stained, with a relatively larger amount of pale and vacuolated nongranular protoplasm. A few red blood corpuscles and polymorphonuclear leucocytes are found scattered here and there outside the blood vessels. The ganglion cells of the anterior horns are few in number; most of those remaining present various degrees of degeneration, but occasionally a healthy cell can be found in the most intensely affected areas, while on the other hand they are generally less affected in the less diseased parts. All degrees of changes can be seen from a beginning chromatolysis to total destruction. A few small round cells are found collected about the periphery of the ganglion cells, but it does not appear to be a definite neuronophagic process. The cells of Clarke's column are similarly affected, but much less so than those of the anterior horns.

With the Wiegert method the nerve fibers are widely separated and swollen; many are broken and present a varicose appearance. The anterior and posterior roots are pale. There is a perivascular cellular infiltration of the white matter, chiefly at the terminal portions of the blood-vessels in the anterolateral columns near the anterior horns. The axis cylinders and neuroglia cells are somewhat swollen. There are no definite foci of the inflammatory cells apart from those about the vessels. The posterior and posterolateral columns of the white matter are little affected.

The pia is infiltrated with small mononuclear cells, chiefly on the anterior surface, but the infiltration can be traced to the posterior surface as well. The blood-vessels of the pia are filled with blood corpuscles, and their walls are slightly infiltrated.

Sacral Region.—The appearances are similar in every respect.

Thoracic Region.—Here the process is the same, but the pia on the posterior surface has escaped.

Cervical Region.—The pia is slightly affected about the anterior surface in close relation to the artery of the anterior fissure. The gray matter of the anterior horns is much less involved than that of the lumbar region, and the posterior horns are little affected. The anterior horn cells are few in number and are similar in appearance to those of the lumbar cord. There is only very slight perivascular infiltration of the blood-vessels in the anterolateral columns of the white matter.

Medulla Oblongata.—In the gray matter a few distinct, small, and recent hemorrhages can be seen, and to a less degree in other parts. The walls of the blood-vessels here and there show slight cellular infiltration. The white matter here, as in the spinal cord, was much less affected than the gray. The cells of the twelfth nucleus were for the most part entirely normal, but a few were somewhat misshapen and stained poorly by the Weigert method. The cells of the seventh nerve nucleus were little affected.

Pons.—There is a slight diffuse cellular infiltration with some perivascular infiltration of small round cells, but much less marked than that seen in the medulla oblongata and the spinal cord.

Cerebral Peduncles.—A slight perivascular infiltration of small round cells could occasionally be found in the gray matter.

Paracentral Lobule.—Here there was a slight perivascular infiltration and also a slight cellular infiltration of the pia.

Cerebellum.—The pia is slightly affected, and there are a few small hemorrhages in the cortex.

Optic chiasm and cranial nerves showed nothing abnormal.

Cauda Equina.—The blood-vessels here were filled with blood corpuscles, and a few small round cells were occasionally seen infiltrating their walls.

The peripheral nerves and spinal ganglia were not examined.

Case II.—P. M., adult Italian. The patient was brought to the Pennsylvania Hospital September 4, 1907, in an ambulance, complaining of pain in his head, back of neck, both thighs and legs, lasting four days. He was constipated; the bowels had not been moved for three days, and he had not voided urine for twenty-four hours. His temperature was 103 3-5; pulse 104; respiration 36. He was unable to move his lower extremities. His bowels appeared to have been paralyzed, but there was no loss of sphincter control.

Physical Examination.—Patient is a well developed, fine looking Italian. Face is flushed; pupils are equal and react to light and in accommodation; conjunctivæ are injected; tongue is protruded in the mid-line, and there is slight fibrillary tremor; there is no pulsation in the vessels of the neck. The chest is well formed, very muscular and with good expansion. Respiratory movement rather rapid but not labored. Radial pulses are equal, rapid and of good volume. The abdomen is soft and tympanitic. The lower quadrant was greatly distended before catheterization, when thirty-nine ounces of urine were removed, after which the abdomen was everywhere soft. He complains of much pain about the costal margins. There is absolute paralysis of both lower extremities, with loss of tendon reflexes. No ankle clonus; and there is a flexor response on irritation of soles of feet. Both feet are held in partial extension. There is a suspicious Kernig's sign of both legs. The upper extremities are somewhat weaker than normal and slightly spastic. There is no impairment of sensation and no loss of sense of position. At 8:20 P. M. on the same day he requested that his thighs be flexed on the abdomen and knees externally rotated until the thighs made an angle of nearly forty-five degrees with the trunk and the legs flexed on the thighs, the feet resting on the bed. He seemed more comfortable in this position. Later, at 9 P. M., his body was cold and he was perspiring profusely, although his temperature was 103. During the sponging which had been ordered, it was noted that his finger tips were cyanotic and the pulse rapid. When the temperature was being taken by the mouth at 10:05 P. M. he became very cyanotic and frothed at the mouth, both arms were moved toward his head, and there was a distressed expression about the mouth. The right arm, hand and

fingers were twitching, but there was no movement of either leg or toes. The pulse was rapid but strong. Artificial respiration was begun, and it was found that the arms were very spastic. Cyanosis developed when artificial respiration stopped. A mouth gag was inserted and artificial respiration continued. The pulse was very rapid, weak and running. He was given 1-150 gr. of atropine injected into a vein of the arm. The patient died at 10:50 P. M., the fifth day of the disease.

Autopsy 1011.—Hospital No. 1635. Adult Italian, September 4, 1907. Performed by Dr. Crispin.

Anatomical Diagnosis.—Acute endocarditis (mitral vegetations). Congestion of lungs, spleen and kidneys. Fatty degeneration of liver. Persistent thymus.

Spinal Cord Microscopical Examination.—Lumbar enlargement. There is an intense cellular infiltration affecting chiefly the gray matter, but the white matter and pia are also involved. In some sections the most marked changes are found in the central and basal portions of the anterior horns, while in others the process is more diffuse, the anterior horns, the posterior horns, and intermediate portions all being affected alike. The blood-vessels are prominent and filled with blood corpuscles, many of which have wandered into the surrounding tissue. The perivascular spaces are filled with small round cells. This is most marked about the anastomotic branches of the anterior spinal artery, which in some sections can be seen cut longitudinally in the gray matter at the base of the anterior horns. The central canal in sections from the lower part of the lumbar cord is almost obliterated, but its outline can be distinguished by the arrangement of the ependyma cells, which appear normal. At higher levels of this region the central canal is wide open and some of the ependyma cells have been torn off. The lumen of the canal is filled with an indefinite, structureless, albuminoid material and a number of round cells. Many of the ganglion cells have entirely disappeared, and many show various degrees of degeneration. They are irregular in outline, the nuclei are indistinct and eccentrically placed, and their dendritic processes are broken. In the anterior and lateral portions of the anterior horns there are numerous separate masses of round cells completely surrounding ganglion cells, heaped one upon another so that the nerve cells can be distinguished with difficulty. The cells of Clarke's column are similarly affected. The nerve fibers are swollen and appear broken and widely separated and varicose. The anterior and posterior roots are paler than normal when stained by the Weigert method. In the white matter there is a cellular infiltration chiefly confined to the perivascular spaces, with some proliferation of the neuroglia cells and swelling of the axis cylinders. The anterior, lateral, and posterior columns are all equally involved, but much less so than the gray matter. The pia is also infiltrated with round cells throughout the circumference of the cord(but it is much more marked about the blood vessels on the anterior surface and along the artery of the anterior fissure. The blood-vessels are filled with blood corpuscles, and their walls are infiltrated with round cells, but this is chiefly confined to the adventitia.

Sacral Region.—Here the appearance is exactly the same, except that the ganglion cells are fewer in number and the grouping of round cells about those remaining is less striking.

Thoracic Region.—This portion of the cord presents much the same appearance as the lumbar region, but the pia is less affected, and the grouping of round cells about the ganglion cells is also less marked here.

The cervical swelling is similar to the lumbar portion, but in addition there are a few small open spaces in the gray matter where the tissue has dropped out.

Medulla Oblongata.—Although much less than in the spinal cord, inflammation can be found throughout the medulla oblongata, especially in the gray matter about the fourth ventricle and in close relation with the blood-vessel, particularly those passing from the anterior surface through the raphe toward the gray matter. The white matter is slightly affected. The cells of the nuclei of the cranial nerves are also slightly affected. The pia is infiltrated with round cells and the adventitial coat of the blood-vessels also somewhat infiltrated.

Pons.—There is a considerable infiltration in the region of the sixth nucleus, and its cells are much diseased, but in other respects the changes here are much the same as those of the medulla oblongata.

Cerebellum.—A few small hemorrhages can be seen in those parts which were in close relation with the medulla and pons.

Basal Ganglia.—A few scattered perivascular infiltrations can be found here.

Postspinal Ganglia.—There are many round cells scattered between and about the ganglion cells, many of which show degeneration. With the Weigert method they appear yellowish and some nearly black; the nuclei of many are indistinct, eccentrically placed, and some have disappeared. There are numerous black colored granules to be seen generally near the periphery of the cells.

The anterior tibial, sciatic, and median nerves and portions of the brachial plexuses showed nothing abnormal.

Case III.—J. F., twenty-five years old; admitted to the Pennsylvania Hospital September 25, 1907. His family history was negative. He had always been healthy. He had been occupied as a day laborer, which he had not been used to, and he attributes his condition to overwork. He first noticed numbness of his feet September 23, 1907. The next day, after helping to lift some heavy boxes, his legs suddenly gave way under him, and he entirely lost control of them, and there was some disturbance of the functions of the bladder.

Physical Examination.—On admission: temperature 102; pulse 102; respirations 48. Anemic looking man with flaccid paralysis of both lower extremities. Some stiffness and aching of the muscles of the neck, and he complained of indefinite numbness of the chest and abdomen. Pupils were equal and reacted sluggishly to light. Eyes, nose, and throat were normal. Glands were not enlarged. There was no pulsation of the vessels of the neck. Chest well formed and expands well. Lungs normal but respiratory movements were greatly increased. Heart sounds weak. No murmur. Abdominal organs all normal. There was complete flaccid paralysis of both legs with loss of tendon reflexes and weakness of both arms. Sensation was normal. Blood count showed hemoglobin, 80 per cent.; leucocytes, 28,650. He died September 26, 1907, the fourth day of the disease.

The spinal cord and a portion of the pons and peripheral nerves were examined.

Autopsy 1018.—Hospital No. 1833. Male, aged twenty-five years. September 26, 1907. Performed by Dr. Donhauser one and a half hours after death. Edema of lungs, congestion of liver, spleen, and kidneys.

Spinal Cord Microscopical Examination.—Lumbar enlargement. There is a marked diffuse cellular infiltration throughout the gray matter; the white matter and the pia are also affected, but to a much less degree. In many sections the anterior horns, the posterior horns and intermediate portions of the gray matter are all equally affected, but in others the posterior horns are less so than the anterior. Inflammatory cells are seen diffusely scattered in great numbers and accumulated in the perivascular spaces. The vessels are only slightly distended and contain few blood corpuscles. Here and there small open spaces are seen when tissue has dropped out of sections. Most of the ganglion cells of the anterior horns have entirely disappeared, but a few still remain which appear much distorted, with an indistinct nucleus frequently eccentrically placed. The dendritic processes of many are broken. In a few sections the inflammatory cells are seen densely packed about the ganglion cells impinging upon their borders. With the Weigert method the nerve fibers seem somewhat more widely separated than normally, but stain well and do not appear swollen except in a few places when in close relation to a blood-vessel. The anterior and posterior roots just after they have made their exit from the cord are paler than normal. The cells of Clarke's column present the same changes as the motor cells of the anterior horns. The central canal appears normal. In the white matter the vessels are distended, and many round cells are seen in the perivascular spaces. There is some diffuse infiltration in the white matter close to the gray matter of the lateral horns, with some proliferation of the neuroglia cells. The pia is infiltrated with cells throughout the circumference of the cord, but the greatest change is seen on the anterior surface. The vessels of the pia are filled with blood cells, and their walls, particularly the adventitial coat, are infiltrated with small round cells.

Sacral Region.—In a few sections the anastomotic branch of the anterior spinal artery can be seen cut longitudinally as it enters the base of the anterior horn of one side, presenting an intense perivascular cellular infiltration. In other respects the appearance is the same as that of the lumbar region.

Thoracic Region.—The gray matter and the white matter are similar in every respect to that of the lumbar region, but the pia is slightly affected on the anterior surface only.

Cervical Region.—Here the process is identical with that seen in the lumbar region, except that the pia is less affected.

Pons.—Only a very few sections from this part were studied, and a few scattered perivascular infiltrations were found, chiefly confined to the gray matter.

The sciatic and median nerves showed nothing abnormal with the Weigert method. The remaining portions of the nervous system were not examined.

The cells taking part in the infiltrations were the same in each case and can be conveniently described at one time.

Under an oil immersion lens when stained with hemalum and fuchsin there were many round nuclei, some very large and others smaller, staining a robin's egg blue color, with a few deep staining chromatic granules and a thin rim of protoplasm. These cells were irregularly scattered and widely separated from one another, never grouped in definite foci.

There were great numbers of cells resembling lymphocytes identical with those found in the pia, generally scattered throughout the gray matter and densely packed in the perivascular spaces, presenting a small, dark-staining, round nucleus and a small amount of nongranular homogeneous protoplasm, also many larger cells with a large paler staining nucleus of almost any shape but generally oval, curved or indented, and a larger amount of protoplasm stained a moderately deep pink color and often vacuolated. Very few polymorphonuclear cells were found, but numerous red blood corpuscles were scattered here and there.

In addition numerous cells were found which did not resemble any definite type and in all probability were undergoing degeneration and would eventually have become typical compound granular cells.

The cases which I have described are typical examples of acute anterior poliomyelitis considering both the clinical and pathological pictures. One case of a child and two of adults, beginning rather suddenly with fever, pain in the lower extremities and back, some rigidity of the posterior muscles of the neck, flaccid paralysis of the lower extremities with loss of tendon reflexes and no sensory changes, bladder and rectal disturbances, the paralysis ascending rapidly, resulting in death following bulbar involvement. The pathological findings are very similar to those reported by Dauber, Goldscheider, Siemerling, Lieppman, Redlich, Risseler, Bülow-Hansen and Harbitz, Sherman and Spiller, Wickman, Harbitz and Scheel, Forrssner, and Sjövell.

Dauber[13] had an acute case in a child that died after five days, presenting infiltration of the pia and perivascular and diffuse infiltration of small round cells in the gray matter, also perivascular infiltration of the ganglion cells and degeneration of the ganglion cells.

Goldscheider[14] found the most intense changes in the anterior horns of the lumbar region, slight degeneration of the anterior and posterior roots by the Marchi method, and degeneration of ganglion cells, and considers poliomyelitis to be a localized myelitis affecting chiefly the anterior horns through the distribution of the anterior spinal artery.

Siemerling[15] studied two acute cases in children and found myelitic changes most marked in the lumbar and cervical regions, with some degenerative changes in the anterior and posterior roots by the Marchi stain, destruction of ganglion cells and slight perivascular infiltration in the white matter.

Lieppman[16] reported a case which developed during a severe attack of furunculosis and died four months later of diphtheria. He agrees with Goldscheider and Siemerling that the process follows the course of the blood-vessels of the anterior horns.

Risseler, quoted by Kahlden,[17] describes three acute cases in which there were various forms of degeneration of ganglion cells with diffuse and perivascular and pericellular infiltration of round cells, particularly in the lumbar region. He upholds Charcot's theory, namely, that acute poliomyelitis is due to a primary change of the ganglion cells.

Redlich[18] reports one case of a child that died on the ninth day. The anterior horns were chiefly affected, but the posterior horns and the white matter and pia also. The infiltrating cells contained many fat granules, which he thinks are typical of inflammation in the nervous system. He also found degenerations of the ganglion cells and of Clarke's column, which he considers to be of two distinct varieties of necrobiosis. There were slight perivascular infiltrations in the medulla, cerebral peduncles, particularly in the tegmentum, none of the cortex itself, but slightly of its pia.

Bülow-Hansen and Harbitz[19] had two fatal cases

and one abortive case, brothers and sisters of the same family, all affected at the same time. Two died on the fifth and seventh day, respectively. The usual changes in the gray matter of the cord, pons, medulla, and slight changes of the cells of the vagus nuclei were found.

Spiller and Sherman[20] reported a case under the title of "Acute Polioencephalomyelitis," presenting the clinical picture of Landry's paralysis and terminating fatally in thirty-eight hours after the appearance of the first definite symptoms of motor disturbance. They found intense cellular infiltration throughout the gray matter of the anterior horns. The pia was also affected, and there were a few perivascular foci within the white columns. The ganglion cells of the anterior horns were much degenerated. Changes extended throughout the spinal cord, medulla, pons, and cerebral peduncles to the basal ganglia, but were not very definite in the cerebral cortex and subadjacent white matter, although even here the vessels were much dilated. They consider that the process was essentially a polioencephalomyelitis, although the white matter was not intact, and that acute anterior poliomyelitis in an adult is similar to that in a child.

The naked eye appearances of the spinal cord and brain in my cases when in the fresh state were similar to those of most recorded cases, consisting only in moderate congestion of the cerebral vessels and a swollen and red appearance of the gray matter of the cord when seen on cross section. The membranes of the cord were slightly hyperemic, but no actual exudation was seen.

Microscopically the pia was infiltrated with mononuclear cells, particularly on the anterior surface, and always most marked in the lumbar region. This was found throughout the length of the cord, gradually diminishing from below upward. In Cases I and II it was distinct about the medulla oblongata and pons, and traces could be found over the cerebral cortex. Rarely a few inflammatory cells were found on the outer surface of the pia. Buzzard[21] has called attention to this fact, which is in harmony with the absence of a true meningeal exudate visible to the naked eye in poliomyelitis, and in contrast with what is generally seen in cases of acute septic meningitis. However the involvement of the pia is sufficient to explain the rigidity of the muscles of the neck and pain and soreness of the lower extremities, which are not uncommon in the early stages of most severe acute cases of poliomyelitis. There was no definite relationship between the intensity of the changes seen in the pia and the changes in the gray matter. In Case II there was considerably more perivascular infiltration of the vessels extending through the posterior white columns of the lumbar cord than in the other two cases, and here the pia on the posterior surface also showed greater changes.

Harbitz and Scheel[22] found in their cases that foci in the cord with perivascular infiltration corresponded to the areas of inflammation in the pia at the same level, while on the other hand inflammation of the pia could be found without any inflammation having developed in the cord at the same level. Therefore, they are convinced that inflammation begins in the pia with a simultaneous infection of the cerebrospinal fluid and extends into the cord along the vessels.

The walls of the vessels about the anterior surface of the cord were slightly infiltrated with mononuclear cells, chiefly confined to the adventitia. Wickman[23] found that the veins were more affected than the arteries; in my cases, however, there was little if any difference. Unlike Batten's[24] cases there was never any evidence of thrombosis.

A marked perivascular infiltration of the branch of the anterior spinal artery as it extended into the anterior median fissure was always found, and frequently this could be traced along its anastomotic branch as it extended into the base of the anterior horn of one side.

Throughout the length of the spinal cord the gray matter was always intensely diseased, the anterior horns suffering more than the posterior, except in a few sections of the lumbar region from Case II, where there was little difference. Degeneration of the ganglion cells was very marked, extending over large areas. Generally the degree of degeneration and destruction corresponded to the intensity of the disease in the surrounding structures. Occasionally after a careful search a healthy looking ganglion cell was found in the midst of a severely affected area.

Interstitial and parenchymatous changes were both marked and were found side by side. Severe degeneration of ganglion cells was never found far distant from interstitial changes: generally where interstitial changes were less marked ganglion cells were not severely diseased.

In Case II neuronophagia was very striking, always confined to the spinal cord, particularly in the cervical and lumbar regions. In Case III it was occasionally found in slight degree. No attempt was made to trace the various stages of this process in detail; the general appearances, however, were very like those described by Forrssner and Sjovell[25] in two acute cases of poliomyelitis.

In the cervical and lumbar enlargements and especially the sacral region they found many ganglion cells completely submerged beneath heaps of round cells; also round cells were seen after having penetrated into the substance of the ganglion cells. As the process advanced the ganglion cells degenerated and the round cells had gained in the quantity of their protoplasm at the expense of the ganglion cells.

They believe that healthy ganglion cells are never attacked, but that there is some chemical substance generated during the course of the disease which has killed or decreased their vitality and which has a positive chemotactic action for the round cells, and therefore they attack the ganglion cells and complete their destruction.

Neuronophagia unquestionably plays a very important part in the destruction of ganglion cells in certain cases of poliomyelitis. In the most intensely affected parts of the gray matter it was never found, therefore one might infer that the process had been already completed and is one of the earliest changes to take place. Forrssner and Sjövell suggest that it may explain the very rapid and sudden onset of paralysis. On the other hand early acute cases have been examined with marked degenerative changes of ganglion cells and no evidence of neuronophagia, so that we must admit that there may be some other cause for the rapid destruction of ganglion cells which as yet we know little about. The posterior spinal ganglia were only examined in Case II; moderate degenerative changes were found. After a careful search of the literature I have been able to find but one reference to examinations of the spinal ganglia in poliomyelitis. Forrssner and Sjövell, in the same article which has already been quoted, describe finding a few round cells outside but in close relation with the small blood vessels and no changes

in the nerve cells. On account of so slight a lesion they assume that this may explain the preservation of sensation.

We as yet have little definite knowledge as to the manner in which lesions found in poliomyelitis are produced. Many observers believe that the infectious agent is carried to the anterior horns of the gray matter by way of the anterior spinal artery. In many instances the distribution of the lesions in the gray matter corresponds very closely to the distribution of the blood vessels. The white matter, on the other hand, is but little affected, and here the blood supply is derived from the smaller vessels extending inward from the pia. Kadyi[26] has shown by his experiments that there is no definite anastomosis between the area supplied by the anterior spinal artery and that supplied by the pial vessels, and that there is an area along the adjacent borders of the gray and white matter which is partly supplied with blood by one and partly by the others. Wickman is inclined to favor the lymphogenous route of infection as most probable, and refers to the similarity of rabies and poliomyelitis.

If we accept the teaching that true perivascular lymph channels do exist, we can understand how lymph-borne infection may cause lesions corresponding to the distribution of the blood-vessels of the nervous system similar to those frequently found in acute anterior poliomyelitis.

Conclusions.—(1) Acute anterior poliomyelitis is essentially an acute polioencephalomeningomyelitis.

(2) The process is the same during infancy and adult life.

(3) The process is most marked in the lumbar and cervical enlargements of the cord and frequently may extend upward as far as the cerebral cortex.

(4) Interstitial changes predominate and occur together with parenchymatous changes. Parenchymatous changes never occur without interstitial changes.

(5) The localization and intensity of cellular infiltration depend upon the distribution and vascularity of the area affected.

(6) Neuronophagia is an important factor in the destruction of ganglion cells.

KAOLIN AS A REMEDY.*

By GEO. RICHTER, M.D.,

St. Louis,

Formerly Professor of Physiology, Beaumont Hospital Medical College.

In 1906 Prof. Julius Stumpf of Wuerzburg recommended the use of kaolin in a book, "Ueber ein zuverlaessiges Heilverfahren bei der asiatischen Cholera sowie bei schweren infectioesen Brechdurchfaellen und ueber die Bedeutung des Bolus (Kaolin) bei der Behandlung gewisser Bakterien-krankheiten," published—Wuerzburg. According to a report by Hahn of Munich in the *Muenchener medizinische Wochenschrift* (Jan. 15, 1907), the author has given kaolin internally in gastroenteritis of children and in cases of cholera (in Prussia, 1906), where in the ten cases so treated a favorable result was obtained. He recommends his method in cholera morbus, typhoid fever, cholera asiatica, ptomain-poisoning, and poisoning by metals. Experiments on dogs showed that doses of white arsenic of 1.2 and 3.5 grams mixed with 40.0 grams kaolin and given within 11 days did not poison the animals. He gives kaolin doses of 125 grams stirred in 250 c.c. of cold water, to be swallowed at once or at short intervals. The same dose is repeated if necessary after three hours. Children should take 60 grams in 125 c.c. water, infants 30 grams in 70 to 100 c.c. water in the nursing bottle. Nothing but a little water must be taken within the next 18 hours. Stumpf believes the effect to be due to a starving of the bacteria by their being enveloped in the mass of the powder. Hahn, however, states that the inhibitory effect in arsenic poisoning is not thereby explained, and his opinion is that kaolin forms a protective layer on the mucosa.

The same journal prints in the issue of Nov. 26, 1907, a paper by Goerner on the same subject. He relates the many experiments made by various investigators in treating wounds, ulcers, etc., with kaolin. Megele noticed the inhibitory effect of the same upon bacteria "due to a drying action." Other authors have held that kaolin is "a reliable aseptic dressing powder." Stumpf disputes Megele's theory, for a watery mixture of an insoluble substance cannot possibly have a drying action. According to him kaolin in powder form consists of particles smaller than bacteria, and it is the enveloping of the bacteria which prevents a further development of the disease. That even very large quantities may be harmless Stumpf proved by taking 250 grams of kaolin every morning for a number of days without any ill effect. Goerner treated 8 cases of acute gastroenteritis, including one case of severe fish-poisoning, with kaolin, with an almost immediate recovery. Of 30 cases of a milder type of acute gastric catarrh only 3 cases were not relieved promptly. Similar results were observed in

*Paper read before the Verein Deutscher Aerzte, St. Louis, April 10, 1908.

the treatment of infants, with the exception of such chronic cases where large masses of mucus were present. He has also observed that any admixture, like sugar or milk, interfered with the result. Diarrhea in grippe was equally well influenced by kaolin. In one case of rectal diarrhea prompt cure was effected by an injection of the mixture. Cases of enteric tuberculosis were also much benefited by kaolin, a repetition of the dose becoming necessary only every few days; the same was true in a case of amyloid of the intestines. In typhoid fever the bacilli disappear from the stool, but otherwise the course of the disease is not influenced much excepting the regulation of the bowels. Goerner recommends kaolin as an excellent corrigent in various forms of meteorism, though here the dose must be repeated at times.

I have not seen any other literature on the subject, but believe the matter would be well worth further investigation, particularly as all the theories advanced are unsatisfactory.

Kaolin (or "argilla, terra alba, bolus alba, china clay, porcelain earth," in a less pure condition also known as "Fuller's earth") has been used as an external remedy for centuries. Internally it is used frequently as an excipient or diluent of silver nitrate and potassium permanganate; chemists use it as a clarifier. It is an aluminum-silicate derived from feldspar by weathering. The ordinary clay consists largely of the same substance. It is insoluble in water, cold acids, and caustic alkalies, and mixes readily with water. Together with other admixtures, it is the cataplasma kaolini of the pharmacopeia. Its action as a cataplasm is solely by its virtue of detaining heat upon the surface upon which it is applied. Taken internally, it cannot exert a heat-retaining action, nor possess a drying effect, as little as carbon which had been exposed to the atmosphere will absorb any gases after it has been saturated with them.

Under the microscope the preparation consists of very fine fragments of crystals of the size of erythrocytes, many still smaller, very few of the size of bacteria. Mixed with some old distilled water I could observe the water-microbes in their usual lively motion for hours. There was certainly no bactericidal action in evidence.

I sterilized a portion by exposing to dry heat of 150° C. and applied it first in a case of chronic urethritis as an injection. The patient was a robust young man who had been infected for the first time in March, 1907. Successively he had been treated by a number of specialists by means of injections, soluble bougies, instillations, irrigations, internal remedies, etc. Nine months later there was still considerable discharge, which consisted of leucocytes, few erythrocytes, and numberless bacteria of many kinds, to the exclusion of gonococci. The two-glass test showed turbidity in both and numerous shreds. Per rectum the prostate was found slightly swollen and tender, also both vesiculæ seminales were sensitive. No spermatozoa were found in the discharge. He had had no epididymitis. On January 7, 1908, I injected kaolin. After 12 hours there was a profuse discharge of pus without the least pain or discomfort. The pus consisted of leucocytes, erythrocytes, and gonococci, partly within the leucocytes, partly in the plasma (gram-negative.) No other microbes could be discovered. In relapses of gonorrhea the reappearance of gonococci, together with the disappearance of the other bacteria, is often observed. On January 10 there was still considerable discharge. Another injection of kaolin was made. Jan. 14, hardly any discharge. The now mucous secretion showed a remarkable number of epithelial cells with two nuclei. The shreds in evidence formerly had disappeared. Jan. 16, another injection of kaolin. Jan. 19, no secretion. Feb. 2, cylindrical epithelium in secretion, much mucus, few leucocytes, no gonococci. Feb. 9, kaolin injection followed by abundant secretion of pus with gonococci. Feb. 14, little discharge containing a few gonococci. Feb. 16, pronounced phosphaturia, which desisted with a more liberal diet. Feb. 23, kaolin, and again Feb. 26. From now on the gonococci grew less and soon disappeared entirely, in spite of many more injections of kaolin upon which no secretion of pus followed. A slight discharge due to the prostatitis and consisting mainly of mucus was finally stopped by means of instillations of protargol.

The study of this case shows a mixed infection in chronic urethritis converted into a simple "catarrhal" urethritis; elimination of the gonococci from the deeper strata, new growth of epithelium; waning of the urethal catarrh, and gradual healing of the prostatitis.

Another case of gonorrhea in a young man who had become infected for the third time on March 9 was examined March 16. The patient complained of a burning sensation when urinating and a rather profuse discharge of pus established since the day before. There was a mixed infection with a large number of gonococci. Urine, after washing out the interior urethra, was turbid (acute anterior and posterior urethritis). Injection of kaolin. March 18, secretion much increased but painless, containing gram-negative cocci only. March 19, kaolin. March 21, only the first glass is turbid. March 23, no trace of a discharge. April 6, kaolin; no reaction, urethra "dry." The two previous infections in the same patients had lasted six weeks or longer each time. As repeated infections usually heal more slowly, the cure within eight days seems remarkable.

A 50-year-old robust man had received a scalp wound one inch in length. The skin was not entirely severed. He refused to have the hair shorn or any stitches made. After cleaning the wound carefully I covered it with dry kaolin powder. A loose crust formed, which was removed every day to be replaced by a fresh sprinkling of kaolin. No pus formed; healing was perfect in 6 days without any scar.

A young lady suffering from myelogenous leukemia (diagnosed two years ago) was wounded by glass splinters above the left wrist, receiving two wounds of about ½ inch in length each and rather deep. The attending physician worked for about two hours before he succeeded in stopping the flow of blood with iron chloride. The following day the lady presented herself with firm crusts over the lesions. Twelve days after there were redness, swelling, and pain; pus oozed from below the crusts. After their removal kaolin was sprinkled on. Very firm crusts formed, underneath which one wound was found healed after about five days, while the lower one exhibited fungoid granulations healing only after an application of carbolic acid.

The little satisfactory result was probably due to the bad condition of the blood and the neglect of removing the crusts. The kaolin in the crust cannot exercise its typical effect.

A stout lady, 66 years old, had a relapse of an ulcer of her right leg over the tibia. The limb was swollen, hot, and tender to the touch. There was a vallated, undermined rim around an area of three inches in length and one and one-half inches in width, with a fungous surface of dark blue color and

slimy pus. March 1, a 2 per cent. resorcine-salve was prescribed. March 7, iodoform was applied and a cataplasm of carbolic acid ordered. March 11, much improvement. Ulcer now size of a half dollar; Unguentum Hebræ. March 19, no change; kaolin powdered on. After four days epithelium covered the whole surface. There was certainly a tendency to heal, but the rapidity with which the closing of the ulcer was accomplished was remarkable. No pus was secreted in this instance.

A laborer, 43 years old and of poor constitution, had an ulcer above the outer ankle on both legs. He had been treated for years without success. Kaolin healed the one ulcer rapidly, while the other one did not seem to be influenced much. Here continuous exposure to direct sun-rays had a satisfactory result.

A lady, 28 years old, had been infected with lues. The symptoms were very severe from the start and subsided only gradually under treatment with intramuscular injections of mercury. After two years she had to be taken to a hospital while suffering from a complication of nervous symptoms. From a bed-sore sprung an erysipelas and phlegmonous inflammation of both limbs with consequent destruction of both knee-joints. There appeared blue pus with *Bacterium pyocyaneum* in pure culture. Kaolin was injected into the abscesses. The watery, flocculent pus was changed into a thick, creamy fluid within twenty-four hours and no bacteria could be cultivated from the discharge.

A clerk, 29 years old, was much troubled by eructations of an extremely foul odor for years, and neither diet nor internal antiseptics afforded any lasting relief. He was given 125 grams kaolin in cold water on the empty stomach. The odor disappeared promptly and has not returned in three months.

A laborer, 49 years old, of cachectic appearance and complaining of persistent pressure pains in the pit of the stomach, no vomiting, acidity 94 after test-breakfast, no blood in feces (guaiac, benzidin, and aloin tests), no palpable tumor, but considerable enlargment of the left lobe of the liver, was relieved of the hyperacidity after a full dose of kaolin. No improvement otherwise.

These are but only some scanty observations which I have reported, still a few conclusions may be drawn from them.

Kaolin evidently causes a leucotaxis, an emigration of leucocytes out of the blood towards the deposit of kaolin wherever the surface is broken, with the formation of "pus bonum et laudabile." The leucocytes carry with them the microbes out of the depths, out of their recesses within the deeper tissues. This is probably due to a mechanical irritation caused by minute spicula, the fragments of crystals which will not perforate normal epithelium, yet wound the softer membranes of other cells. This is, however, only a theory, as I could not observe it under the microscope; at any rate it cannot be due to any chemical or other physical process, like coagulation or osmosis, as kaolin is absolutely indifferent to organic bodies.

The leucocytes destroy most of the bacteria by phagocytosis, with some exceptions, *e.g.* gonococci, which, while being eliminated, prey upon the carrying leucocytes. There may be another agent active in this process: ferments secreted by or with the leucocytes digesting the microbes.

Internally taken kaolin acts probably in the same manner, as a mild mechanical irritant. It must always be given in very large doses because it has a large surface to act upon. It inhibits the bacteria from receiving any pabulum as soon as they have been mixed with the inorganic masses. But enough of those rapidly propagating cells will still adhere to the mucous membrane to do serious harm if some other agent does not become active and interfere with their growth. Such agents are probably the leucocytes and ferments secreted with them. The experiments demonstrating the digestive affects of leucocytes upon culture media are well known, as also the fact that eventually they may not exert such an action (in certain cases of leukemia). That arsenic in large doses mixed with kaolin had no poisonous effect in Stumpf's experiments may be due to an insoluble combination forming with the protoplasm of the leucocytes which are enveloped in the kaolin. And this reminds of the observations made with Bier's hyperemia where poisons injected into the tissues are so slowly absorbed that the organism suffers no serious harm. Ferments are not so readily destroyed in the intestinal canal as leucocytes, which are rarely found in the feces, and therefore their determination after taking kaolin would prove interesting. The theory demands, of course, that the kaolin should come in contact with lesioned surfaces which it would irritate, as in all catarrhal conditions.

Now it remains to explain why kaolin produces an abundance of pus in an inflamed urethra and not upon an open ulcer. Perhaps the number of leucocytes emigrating is in proportion to the bacteria present. Exposed on an open surface the leucocytes are more rapidly destroyed than when confined in a cavity. The establishment of epithelium repels the leucocytes. The dry powder absorbs all moisture promptly.

There is after all nothing new in the theory, in the principle propounded. Similar remedies are used extensively of whose action we have not understood the true cause yet. The ordinarily insoluble bismuth subnitrate, which taken in small doses or enveloped in media preventing its mechanical effect seems to be inert, consists of minute crystals which must possess an irritating effect. Zinc oxide, iodoform, carbon, calomel, talcum, and others belong in the same class. Most of those substances are, however, not always indifferent and may become harmful, which kaolin never does. The only admixture permissible is pure water, for the reasons stated.

Kaolin should be tried in the internal diseases named and also in cases where free communication with the surfaces exists and a formation of crusts is obviated in fetid abscesses, diseases of the nasal cavity, urethra, rectum, vagina, and perhaps also in cystitis. An essential point may be that the blood is of a healthy character. In cachexia not much can be expected.

In infectious diseases our first endeavor is to destroy and eliminate the virus, the next to prevent further infection by antisepsis and asepsis. It appears that both functions are fulfilled by the leucocytes. Kaolin produces an emigration of leucocytes toward the injured parts, without causing more irritation than the organism desires.

A closer study of the leucocytes and of the ferments somehow connected with them promises a better understanding of the "vis medicatrix naturæ."

SOME OBSERVATIONS ON THE URETHRAL LENGTH.

By WALTER S. REYNOLDS, M.D.,

NEW YORK.

CHIEF OF CLINIC AND INSTRUCTOR IN GENITOURINARY DISEASES, COLLEGE OF PHYSICIANS AND SURGEONS (COLUMBIA UNIVERSITY).

At the outset of this paper I wish to state that nothing new or contradictory of the already established conceptions of the anatomy of the urethra has been attempted. The examinations were undertaken to satisfy myself in regard to statements in works on genitourinary diseases concerning urethral measurements. Such studies, if only confirming established ideas, may not be without interest, and with that thought alone in mind this paper has been prepared.

Nearly everyone has probably at some time attempted to make use of urethral measurements as an aid in diagnosis, especially in prostatic disease. After failing in several cases to obtain satisfactory information where urethral measurement was employed, it was decided to examine a series of cases with a view of ascertaining how far it was possible to use this method as an aid to diagnosis, and to see how closely results might correspond with those of others.

It is seldom necessary, perhaps, to resort to this method for accurate diagnosis; still there are cases in which all means at our command must be employed to arrive at satisfactory conclusions, and if it is possible by so simple a means as urethral measurements to determine abnormalities in this or closely related structures, it should not be neglected. Nothing it would seem could be easier than to determine by measurement the urethral length, and by comparison with known standards to draw fairly correct deductions. However simple in theory this may seem, in actual practice it is not so easy to make accurate measurements, and this may account for some of the seeming inconsistencies in some of the cases examined.

Before we are in a position to state whether we have an abnormality in the urethral length we must have a clear conception as to the normal urethral measurement, and if possible definitely fix on standards of comparison. In endeavoring to settle this point we find, while there is some diversity of opinion on the question, most writers are firmly in accord, and it would seem superfluous to go over the subject, but rather to direct our attention to abnormal conditions. On consideration, however, it was thought better to conduct an independent investigation of the whole subject, starting with normal conditions and thus, if possible, fix our own standards of comparison, rather than accept those already given. This paper will therefore only deal with urethræ in which fairly normal conditions might be expected to prevail.

The majority of the men examined were dispensary patients who were being treated for chronic urethritis or who had had that disease, but whose prostates were normal so far as could be ascertained by rectal examination, and where stricture or other abnormality which might interfere with accurate measurement, could be excluded. It can, of course, be said that these were not normal urethræ, but in dispensary cases urethræ which have not been affected with urethritis are rare, except in younger subjects, and as we are dealing with adult conditions such material as was at hand must be utilized for the purpose.

Before considering the cases examined a brief review of the subject of urethral measurements may not be out of place. A majority of works on genitourinary diseases probably follow the descriptions of the urethra as given in anatomical textbooks. These are, of course, post-mortem measurements, and the difficulties of making accurate measurements would not be so great as on the living subject, but at the same time it might not give the same results as would be obtained during life, as will be shown later.

Gray states "the urethral length is from 8 to 9 inches; of this 1¼ inches is prostatic, the membranous being ¾ of an inch along its upper, and ½ inch along its lower surface, in consequence of the bulb projecting backward beneath it below." Thompson, in his work on stricture, from an examination of sixteen post-mortem specimens, gives the following measurements: Spongy portion 6½ inches; membranous ¾ inch; prostatic 1¼ inch; total length 8½ inches. He then mentions the investigations of Mr. Briggs of the Lock Hospital, which were carried out on the living subject, and who found the urethral length to be about 7½ to 7¾ inches. These measurements were confirmed later by Thompson and are given as from 6½ to 7¼ inches. Attention is later called to the difference in post-mortem measurements, which is given as 8½ inches, and on the living subject as about 7 inches.

Thompson says in speaking of prostatic hypertrophy that "the prostatic urethra may measure 4 inches in prostatic hypertrophy, instead of 1½ inches, its normal length," and further, "If by examination the catheter has traversed not more than the ordinary distance, say from 6½ to 8 inches, we may be satisfied that prostatic enlargement does not exist. But if the catheter has passed easily, say 9 or 10 inches, and still no urine flows, there will be little doubt of the presence of prostatic enlargement."

A point which must also be taken into consideration in urethral measurements is the distention of the bladder with urine and its effect in overcoming the muscles controlling urination. If, as generally stated, when the bladder becomes distended with urine, the presence of the fluid in the bladder overcomes the resistance of the internal vesical sphincter, and the prostatic urethra becomes part of the bladder cavity, the urethral length must be correspondingly shortened. On this point White and Martin say: "The discharge of urine from the bladder is prevented by the tonic contraction of the muscular apparatus of the membranous and the prostatic urethra. As the bladder becomes distended, the internal vesical sphincter yields, and the urine enters the posterior part of the prostatic urethra, causing a desire to urinate, which is resisted by the action of the voluntary fibers of the external vesical sphincter and the compressor urethra. On passing a catheter when the bladder is full, the urethra seems about an inch shorter than it does immediately after micturition; this is owing to the participation of the prostatic urethra in the retentive function of the bladder."

It would be interesting to speculate as to what effect prostatic enlargement has, if any, on the action of these muscles. If there is no change we should be led to believe that in prostatic hypertrophy, where there is usually more or less residual urine, a diminution of urethral length would be found in some cases. Since this paper deals only with normal urethra it would be out of place to consider the subject further.

The method of examination to determine the urethral length in these cases was as follows: The

man after voiding urine was placed on a table and the penile length determined, measuring from the integument over the symphysis pubis to the apex of the glans penis; a bougie *à boule* was then passed to the anterior layer of the triangular ligament, care being taken that the same penile length was maintained, as it was in all subsequent measurements. This is important because there may be considerable variation in this respect during examination if care is not taken. The man then stands, while a soft rubber catheter No. 12 French is passed, and when the few drops of urine which ordinarily flow, make their appearance, the distance from the meatus to the eye of the catheter is taken. To determine the urethral length with the bladder distended, a catheter is again passed and the bladder filled with fluid. The catheter then being withdrawn until just at a point where the fluid flows, the measurement is again taken as before.

The total number of cases examined was 22; of these, Cases I, II, IV, and V are incomplete, while Cases X and XIII are prostatics, leaving 15 cases for study.

A glance at the table shows considerable variation in the individual urethral lengths, but when we come to determine the averages, the results are nearly those given by Briggs and quoted from Thompson's work; thus the penile length is in the 15 cases about 2¾ inches (2.78); the length of the anterior urethra 5½ inches; urethra with bladder empty about 7½ inches (7.61 +); while the urethra with the bladder distended measured slightly less, 7.51 + inches.

Taking up the various measurements separately, we find that the penile length averaged about 2¾ inches measured from the symphysis. In Case IV the penile length was 4½ inches, and the total length of the urethra 9¼ inches. This was in a man 43 years of age, who was being treated for prostatitis, and whose prostate was markedly enlarged by rectal touch. He was one of the earlier cases recorded, before the examinations were systematically begun.

TABLE SHOWING MEASUREMENTS OF URETHRA.

XXII	23	3¼	6	8	8	14 oz.	
Av. l'gth	.....	2.78	5.50	7.61+	7.51+		

Case VIII gave a penile length of 3½ inches, while the anterior urethra measured 6½ inches.

Cases XI, XVIII, and XXII all showed a penile length of 3¼ inches, while the anterior urethra measured 5¼, 5¾, and 6 inches respectively; a difference of ¾ of an inch between the longest and shortest anterior urethra, all having the same penile length.

Cases XVII, XX, and XXI, the penile length was 2¾ inches and the anterior urethra in the same cases were as follows: 5½, 5¼, and 4½ inches; giving 1 inch between the longest and shortest. We would naturally expect that the relation of the penile length to that of the anterior urethra would vary very little. Such does not seem to be the case, however, if we concede that the measurements are accurate.

The anterior urethra in one case measured 6¾ inches (Case XII) while the penile length was only 3 inches. The shortest anterior urethra measured 4½ inches. The average of the 15 cases was 5½ inches. The average as given by Gray is from 6 to 7 inches, while Thompson states it as from 5 to 6½, in the quotation already cited. But in speaking of the location of stricture, he makes the anterior urethra measure from 6 to 6½ inches.

In Case II the total urethral length was 9 inches. In this case the measurements were also incomplete. The case was, however, a young man of 25 years where no prostatic enlargement was revealed by rectal palpation. The next longest urethra was 8¾ inches (Case VIII). The anterior urethra in this case measured 6¾ inches, making the posterior urethra measure 2½ inches. Case XV gave a urethral length of 6 inches and an anterior urethra of 4¾ inches. Here the posterior would be 1¼ inch.

The average total urethral length, as already stated, was about 7½ inches.

The posterior urethra varied from 1¼ (Case XV) to 3 inches (Case VI). Here again there seems to be no exact relation between the length of the anterior and that of the posterior urethra.

When we come to a consideration of urethral length as influenced by a distended bladder, my experiments fail to coincide with some of the authorities already quoted; for in nearly every case there was little, if any difference in the measurements taken when the bladder was empty or distended. Whether it was a fault in the technique or not, I am unable to say. I can only state that as much care as possible was taken in making the measurements, and the amount of fluid was as much as is usually found where the Thompson two-glass test is resorted to as a means of diagnosis. Whether part of the prostatic urethra does really become a part of the bladder cavity under these circumstances or not does not render the test of less value in diagnosing infection of this portion of the urethra.

In ten cases the result was the same whether the bladder was distended or not.

Case XI, XVII, and XIX showed from ¼ to ½ inch shortening when the bladder was distended, while Case XIII, a prostatic, and Case XX, both showed an increase of ¼ inch.

In conclusion the writer wishes again to state, that while he recognizes the fact that exact measurements of this sort are in the nature of things extremely difficult or perhaps impossible, it is hoped that the results may not be without interest to others as they have been to himself.

66 WEST SEVENTY-FIRST STREET.

Ankle Drainage.—Bolton presents a very satisfactory and efficacious plan of draining the ankle in cases of severe infection following injury. The plan adopted consists in excising the astragalus and the drainage of the joint through the space so created. The method to be used in establishing the excision varies naturally with the character of the original injury. The writer records very flattering results.—*St. Louis Courier of Medicine.*

MEDICAL RECORD.

New York, September 19, 1908.

CREOSOTE INHALATIONS IN TUBERCULOSIS.

THE treatment of pulmonary tuberculosis at present in vogue is emphatically characterized by therapeutic nihilism, so far as the use of drugs is concerned. Fresh air, overfeeding, and rest constitute the tripod upon which the entire therapeutic structure rests, and except when a dry cough is so distressing as seriously to interfere with sleep, or digestive troubles, induced by the excessive amount of protein forced upon unwilling organs, demand relief, the resources of the pharmacopeia are seldom called upon. Even cod-liver oil, once the mainstay of the tuberculous, is denounced as occupying space in the digestive tract which might better be filled with eggs and milk. (And the possibility, even the probability, that much of the milk may contain the bacilli of bovine tuberculosis seems by universal consent to be ignored.) It is, of course, rank heresy to say aught against the prevailing fashion or to suggest that certain drugs may have a quasi-specific action in this disease, if not against the tubercle bacilli, at least against the pus organisms. Nevertheless there are not a few practitioners of independent views who dare to think that forced feeding may be carried too far and that even fresh air and rest may be supplemented by medication with benefit. The results of sanatorium treatment, except in the incipient stages, are not so brilliant as to justify the prevailing belief that nothing else can be done for the tuberculous. The educational value of the sanatorium cannot be questioned, but it is permissible to ask whether, in its exclusive reliance upon nature's remedies, it is not neglecting some valuable artificial means of combating the disease. When confronted with a case of bronchitis or of pneumonia the physician, unless he is an avowed therapeutic nihilist of the most advanced Oslerian school, does not hesitate to turn to the materia medica for remedies to relieve the prominent symptoms, if not to attack the disease directly, and if he has chosen his remedies wisely the patient profits by his therapeutic faith. May it not be that we have gone too far in our rejection of medication in tuberculosis?

In an article on "Laryngeal Tuberculosis," in the *American Journal of the Medical Sciences* for August, Dr. Beverley Robinson renews his plea for the use of creosote inhalations, not only in the laryngeal, but also in the pulmonary, localization of tuberculosis. He first directed attention to antiseptic inhalations in tuberculosis, in a paper read before the Climatological Association in 1885, and since that time has repeatedly, in journal articles and remarks before societies, urged the palliative and even curative value of this method in the treatment of the disease. The inhalations are given by means of a perforated zinc mask, worn continuously, the pad being moistened with beechwood creosote and alcohol, to which, when there is much irritative cough, a little spirit of chloroform is added. After an experience of twenty-five years with this method, the author asserts that he knows of absolutely no other means which will afford anything like the same amount of relief to symptoms and hasten and promote cure to the same degree. The late Dr. Austin Flint gave testimony, many years ago, to the value of this method of treatment, and others in this country and England have also spoken with confidence of its efficacy.

A theoretical objection has been raised against the use of inhalations in pulmonary complaints that the medicated vapor cannot penetrate to the alveoli of the lungs so as to act directly upon the focus of disease. But even if the vapor does not reach the lungs in the inspired air, it may do so through the blood circulation. It is possible the therapeutic action of the creosote would be exerted equally if the drug were given per os, and indeed it is often so given with apparently beneficial results. When the drug is given by inhalation, however, the stomach, already burdened with an excess of food, is relieved of the task of disposing of it, and, theory to the contrary, it may reach the lung more directly if inhaled. Dr. Robinson believes that a most valuable therapeutic adjuvant, if not a specific remedy, is neglected when creosote is not given, preferably by inhalation. The results which he and others who have employed the remedy for these many years have obtained would seem to make it worthy of the notice of phthisiotherapists. A renewed trial of it could hardly do harm when other remedies fail—and, alas! other remedies often do fail in the treatment of tuberculosis.

NARCOSIS AND IMMUNITY.

THE use of ether and chloroform in producing surgical anesthesia always introduces a certain indeterminate factor into the prognosis of any operation, the relative significance of which is very hard to calculate because of the little knowledge we possess of the effect of these drugs upon the organism. In the first place, the functions of very important organs may be profoundly affected, and secondly, the properties of the body fluids may be modified by the anesthetic substances. It is the latter effect which A. H. Zimin of the Tomsk Bacteriological Institute has made the object of a special study, reporting his findings in a monograph issued in Russian by the Institute and entitled "The Influence of Ether and Chloroform Narcosis upon the Bactericidal Power of the Blood and upon Phagocytosis." Platania, Klein, and Cogswell have earlier shown the weakening influence of narcosis upon animals, anesthetized dogs dying after being inoculated with plague while control animals were fully protected by their natural immunity. Bunge showed that the immunity against diphtheria was much diminished by subjecting inoculated animals to nar-

cosis, and Rubin, writing in 1904, showed the unfavorable effect of subcutaneous injections of ether and chloroform upon infected animals.

Zimin studied phagocytosis in anesthetized guinea-pigs, using for this purpose a nonvirulent organism, *Bacillus proteus vulgaris*. In control animals the peritoneal exudate after injection of the culture of this organism was abundant in actively phagocytic leucocytes, no free bacilli being present twenty-four to thirty-six hours after the injection had been made. Other animals were anesthetized and it appeared that the mere procedure was badly borne by them, over one-half dying in consequence of the narcosis. The multinuclear cells were not so numerous in the exudate of anesthetized animals as in controls, and the index of phagocytosis was almost constantly higher in the latter animals, but the healing of wounds made in the technique of the experiments ran about the same course in both series of animals. Studies of the effect of anesthesia upon the bactericidal properties of the blood were made on rabbits, and while a certain diminution of these properties could be observed in consequence of narcosis, the differences were not very marked. On the other hand, the control animals showed frequent individual fluctuations in the bactericidal power of the blood, while the animals subjected to the effect of ether or of chloroform gave more constant though lower figures.

The effects of anesthesia upon the protective processes and phenomena appear to have been very slight in this series of experiments. But it must not be forgotten that the animals used were healthy individuals and the slight changes in their defenses against infection would have been much more significant for their welfare in pathological conditions. The tide for or against recovery may be turned so easily in diseased conditions that the influence of anesthesia, however slight in absolute figures, probably plays a relatively important rôle in the infections which demand surgical interference with the employment of chloroform or ether as a general anesthetic.

THE CARE AND CONTROL OF THE FEEBLE-MINDED IN GREAT BRITAIN.

It seems to be now a definitely established fact that lunacy in all its forms is considerably on the increase throughout the civilized world. That such is the case in this country, so far as figures can be relied on, is certainly true. As bearing upon this vitally important subject, the report of the British Royal Commission appointed in 1904 to inquire into the matter, and which has just been published, possesses an interest beyond the limits of England and Wales.

The report in question is voluminous and is to be followed by six volumes and appendices, embodying the data through which the Commissioners have arrived at their several conclusions. It is estimated that in England and Wales there are at the present time about 150,000 "feeble-minded," in addition to 122,000 certified as insane, making a grand total of 272,000 persons, or in the neighborhood of 0.83 per cent. of the population, who are not responsible for their actions. It is a somewhat curious condition of affairs, that while the liberty of 122,000 is restricted for the good of the community at large, no less than 150,000 should be allowed their freedom. The report contains suggestions for the better care of these unrestrained irresponsible individuals into which, however, there is no space to enter here. It will be sufficient to say that the being at large of 150,000 individuals suffering from varying degrees of mental aberration must be obviously a source of some danger to the whole population. The Commissioners have this to say in regard to the gravity of the existing situation: "The mass of facts that we have collected, the statements of our witnesses, and our own personal visits and investigations compel the conclusion that there are numbers of mentally defective persons, whose training is neglected, over whom no sufficient control is exercised, and whose wayward and irresponsible lives are productive of crime and misery, of much injury and mischief to themselves and to others, and of much continuous expenditure wasteful to the community and to individual families."

With respect to the training of defective children, the Commissioners find an unsatisfactory state of affairs. As a result of medical investigations, the Commissioners conclude that a total of over 36,000 children on the school registers are in need of more suitable provision than is at present existing. On this matter they pronounce as follows: "The educational system of the country, established for the teaching of the normal child, is in our opinion unsuitable for the child who, unlike the blind and deaf, can never reach the mental level of the normal. Also, it is evident that the development of the institutional and other arrangements required for this class would lead education into a department of work largely foreign to it. It is only by taking care of children who are mentally deficient in various ways and degrees as part of a common problem that it becomes possible to provide for them systematically or adequately either during childhood or later. On these grounds it seems to us indispensable that a new authority should be established for the care and control of this class, and that it should be responsible both for children and adults."

It is interesting to learn that the members of the Commission who visited this country for the purpose of inspecting and reporting upon the system of treating the insane and feeble-minded which prevails in many of the States, were greatly impressed by the general superiority of American methods to those which rule in Great Britain. One volume of the series which is about to be published by the Commission will deal wholly with American institutions for, and system of training, the insane and mentally defective.

As to heredity in its relation to defects of mind, the volumes shortly to be published will discuss this phase of the subject fully. The conclusions of the Commissioners as published in the report seem to be expressed somewhat ambiguously. They are made to say that there is the highest degree of probability that feeble-mindedness is usually spontaneous in origin, not due in fact to influence on the parent, and that it tends strongly to be inherited. This appears to be a contradiction in terms, the

more so as the trend of the argument in the report is in favor of the influence of heredity on children born of unstable or of feeble-minded parents.

Operative Treatment of Pulmonary Embolism.

Much has been written in recent years concerning the etiology and treatment of thrombophlebitis. In spite of all prophylactic endeavor thrombi occur and a certain percentage of them is followed by an embolus of the pulmonary artery or one of its branches. When a small branch is involved the prognosis is not necessarily fatal, but when the main artery or one of its two main branches is the seat of the embolus, the case nearly always ends fatally and treatment is of no avail. At the thirty-seventh meeting of the Deutsche Gesellschaft für Chirurgie Trendelenburg suggested operative treatment for embolism of the pulmonary artery or one of its two main branches. He held that death frequently did not set in for from ten to sixty minutes after the onset of the attack, thus allowing sufficient time for an operation. He advised making a skin-rib flap and opening the pleura and pericardium. The origins of the pulmonary artery and of the aorta are then compressed by temporary elastic ligatures, the pulmonary artery is opened, the embolus is detached, the wall of the artery is closed by suture, and finally the ligatures are removed. The entire procedure from the moment that the ligatures are applied until they are removed must not take longer than forty-five seconds, as the patient would otherwise die. After numerous animal experiments Trendelenburg performed the operation once on a human being, but without favorable result. To say the least such surgery is heroic and is therefore necessarily followed by a high mortality. It also has the objectionable feature that a part of the operation must not consume more than three-quarters of a minute if the patient is to survive. Furthermore while it is often easy to differentiate between an embolus of one of the pulmonary arteries and an embolus of one of its smaller branches, this is not always the case, and the operation would be useless if the latter were involved. Then we must consider the remote possibility of a patent foramen ovale which would be a positive contraindication to the operation.

Duodenal Obstruction after an Abdominal Section.

Intestinal obstruction, functional or mechanical, is one of the most serious accidents that may occur after an operation involving the peritoneal cavity. The symptoms often enough simulate sepsis, and the surgeon passes anxious hours in his indecision between the two courses open to him: another laparotomy, which is, of course, a very dangerous procedure, and may prove completely unnecessary, and "expectant treatment," which may let the patient really suffering from mechanical ileus to get beyond all hope of recovery through an operation. In the *Berliner klinische Wochenschrift* for June 15, 1908, Landau considers a special form of ileus occurring after operations, namely, the strangulation of the transverse portion of the duodenum by the root of the mesentery and the superior mesenteric artery contained in the latter. In one of his patients, who had undergone a hysteromyomectomy, symptoms of sudden collapse, with incessant vomiting, meteorism, thready pulse, and the other signs that usually go on with beginning peritonitis suddenly appeared. No general treatment was of any avail, and an operation was decided upon, when it occurred to one of the attending physicians that duodenal obstruction could produce a similar symptom-complex. On his advice, the patient's position was changed from the usual dorsal decubitus to a prone one, so that the supposed pressure upon the bowel would be relieved. The effect was instantaneous; the vomiting ceased, the abdominal distention went down, the pulse improved—in a word, complete and speedy recovery followed. A similar case, occurring later, was correctly interpreted soon after the beginning of the symptoms, and the same simple procedure, the change of position of the patient, was followed by a like favorable outcome. Landau thinks that the duodenum is naturally exposed to pressure, because it has no mesentery and is in reality a fixed portion of the intestines. Normally, however, the digested material from the stomach, and the secretions of the liver and of the pancreas keep it almost always half-filled and prevent its collapse, with the possibility of further compression caused by the tug of the intestines upon the root of the mesentery. Such pressure in the healthy man may produce a momentary nausea and a feeling of uneasiness, and change of position quickly relieves them. The usual postoperative treatment, however, the withholding of food, the flat posture on the back, combined with the paralyzing effect of the anesthetic, furnish all favorable conditions for producing collapse and compression of the duodenum. Landau thinks that the practice of allowing patients to leave their beds as soon as possible after an abdominal section, which practice has been warmly defended by several American surgeons, is the best method of preventing this serious complication. Both his patients were kept in bed longer than usual, because of special indications, and the occurrence of duodenal ileus in their cases strengthens his decision to allow patients to sit up or to leave the bed very early after an operation involving the peritoneal cavity.

News of the Week.

Tuberculosis Campaign.—Free lectures on tuberculosis are being given in Iowa by the Rev. A. E. Kepford of Des Moines, who is reported to receive a salary of $5,000 a year for traveling through the State, lecturing, and distributing pamphlets and tracts. The lectures are illustrated by stereopticon pictures and attract large audiences. Since March 75,000 pamphlets have been distributed. In Pittsburg, Pa., the officers of the Tuberculosis League, which conducts the hospital for the treatment of tuberculosis, have opened a school for the children who are patients, which is held on the porch of the hospital. The school is in charge of an adult patient, a school teacher who has had to relinquish her work. Two short sessions are to be held daily. It is thought by some physicians that there is no better place to cure tuberculosis than on the shore of Lake Michigan. Acting on this belief, and alarmed by the steady spread of the disease in Northern Illinois, physicians of Lake County recently met at Waukegan to effect the organization of the Lake County Anti-Tuberculosis Association. Dr. J. C. Foley of Waukegan, was chosen president, and Dr. W. H. Waterson, manager. It is expected that a building capable of housing fifty patients will be erected near Waukegan at a cost of $10,000. In addition to establishing a colony for patients afflicted with tuberculosis, the Associa-

tion will conduct an educational campaign among the people of Lake County (Illinois), and especially among the farmers. The Association will cooperate with the Chicago Department of Health, which has tried in vain to persuade the farmers to have their cows tested for tuberculosis, and finally has arranged for the sterilization of all milk coming into Chicago.

New York Department of Health.—In submitting its budget for 1909, the department asks for an appropriation of $3,416,519.25, an increase over last year of more than a million dollars. A large part of this increase is requested so that the force of the department may be increased by 485 new employees. The total salary list for 1909 is estimated at $2,269,722.25. The sum of $5,000, which was authorized by the Board of Estimate to be expended in exterminating stray dogs, has been exhausted.

Death Rate in New York—The death rate for the week ending August 29 was 15.15 per 1,000 of population. For the corresponding week in 1907 the rate was 17.92. The total number of deaths was 1,472 in 1907 and 1,284 in 1908. Of the latter number 290 were due to diarrheal diseases.

Medical Inspection.—The summer corps of medical inspectors in Chicago visited seven thousand and ninety-three families in the congested residence districts during the week ended August 29. The 36,298 persons comprising these families were occupying a total of 30,555 rooms. There were 1,746 children under one year of age, 4,364 from one to five years, and 15,535 children were over five years of age. Of the children examined, 341 were found sick.

New Charities Boat.—The service of the new steamboat of the Department of Charities of New York was inaugurated on September 10. The boat will make trips between the foot of East Twenty-sixth street and Blackwell's Island for the use of patients and passengers going to the City Hospital.

Cholera in St. Petersburg.—Reports from St. Petersburg indicate that Asiatic cholera there is rapidly becoming epidemic. Up to September 15 the hospitals had received 240 cases, and sixty deaths were reported to that date. It is feared that the epidemic may reach the dimensions of that which occurred in 1891, when thirty deaths a day were reported during the months of October and November. The cases have been confined chiefly to the lower classes. The conditions prevailing in the suburbs of St. Petersburg are said to be especially favorable for the development of the disease, since in many sections there are no water mains, and the people drink the polluted water from the canals. The German authorities are exercising strict precautions and all emigrants from Russia are being examined with the greatest care.

Suicides in St. Petersburg.—During the first week in September sixty-six cases of suicide were reported in St. Petersburg. A large proportion were said to be working girls between the ages of eighteen and twenty-five.

Opium in China.—The Chinese government has taken its first drastic action under the new regulations covering punishment for the sale of morphine in sentencing, on September 9, a morphine seller of Pekin to banishment for ten years for dealing in the drug. The limit of three months allowed for metropolitan officials to record the fact that they had ceased using opium has passed without a single man coming forward to sign the pledge.

Famine in China.—As a result of the recent heavy floods in China, which have destroyed a large part of the ripe crops, a famine is threatened in the region between the Yellow River and the Great Wall.

Louisiana and Lepers.—The treatment of persons suffering from leprosy is a problem which has been wisely met by the State of Louisiana. A home is maintained there where lepers are under the control of mild and proper regulations, the government being vested in a State Board and the internal arrangements in the hands of a group of Sisters of Charity. The land on which the home is situated was formerly a part of a large sugar plantation, and opportunity is afforded for those who are able to perform useful services. Books, music, and other diversions are provided.

The International White Cross Association, which was founded last year for the purpose of concentrating the fight against cancer, tuberculosis, and other epidemic diseases and social scourges, and of promoting the pure food movement, held its first congress at Geneva during this month. About 700 delegates were in attendance, and attention at this sitting was directed more especially to formulating plans for the regulation of food and pharmaceutical products, and to considering the movements in this direction already under way in America and Europe. By thorough discussion the attempt was made to evolve a fair and reasonable definition of pure food, which would serve as a basis for uniform international legislation against food adulteration.

The Playground Association of America held its second annual congress during the second week in September at the Museum of Natural History, New York. Dr. Maxwell, the City Superintendent of Schools, spoke of the great need, particularly in New York, for recreation centers, and said that the Board of Education needed $200,000 to carry on the work. One of the delegates suggested that certain streets might be roped off during suitable hours and the children allowed to use them as playgrounds. The congress closed with an exhibition of folk-dancing in Central Park on Saturday afternoon. The officers elected for the coming year are as follows: *Honorary President,* Theodore Roosevelt; *President,* Luther H. Gulick; *Honorary Vice-president,* Jacob A. Riis; *Vice-presidents,* H. B. McFarland and Miss Jane Addams.

Alcohol in Berlin.—Dr. Hirschfeld, a German physician, has computed the quantity of alcoholic drink consumed in Berlin, and he announces that during the time investigated the consumption of beer was at the rate of 438,929,532 liters a year, and that large quantities of brandy and wine were also drank. The average annual indulgence in alcoholic drinks per head is estimated on this basis as 236¼ liters, at a cost of about 100 marks. As the average income of the Berliner is less than 700 marks, it may be said that he spends one-seventh of his income for intoxicating drinks.

Central Park Lakes.—Many complaints have recently been printed in the newspapers concerning the condition of the water in the lakes in Central Park, New York, and in consequence Dr. Walter Bensel, Sanitary Superintendent, has, at the request of the Park Commissioner, directed an investigation. In his report he states that while in that portion of the lake known as South Bay there is an accumulation of decomposing vegetable matter such as is inevitable at this season of the year, the condition of the lake is in no way detrimental to the public health. The Park Commissioner has also

characterized as ridiculous the statement, which appeared a short time ago in the daily papers, to the effect that the oil used on the roadways and the gasoline leaking from automobiles were draining into the lake and poisoning the ducks and swans. Post-mortem examinations have shown that deaths among these birds are due either to old age or to tuberculosis.

New Hospital for Evanston (Illinois).—Work has been begun at Evanston on a large new hospital, which is being erected by the Sisters of St. Francis at a cost of $80,000. It will adjoin the old hospital building but is much larger than the present structure and will increase the efficiency of the institution practically three-fold. The plans provide for a four-story brick structure, with stone trimmings, substantially constructed on the best lines laid down by modern medical and surgical science. There will be a general ward, operating room, patients' rooms, nurses' and physicians' rooms, diet kitchens, and all the accessories.

Dr. John A. Wyeth of New York lectured before the Virginia Clay-Clopton Chapter of the Daughters of the Confederacy in Huntsville, Ala., on August 27, on the life and character of General Robert E. Lee.

Dr. E. Franklin Smith of this city has removed to the new physicians' building at 11 East Forty-eighth street.

The American Electrotherapeutic Association will hold its eighteenth annual meeting in the Electrical Engineers' Building, 29 W. 39th street, on September 22, 23, and 24. All practitioners of medicine are cordially invited to attend all sessions. A full program is announced, and it is believed that the exhibit of electrical and .r-ray apparatus will be very complete and interesting.

The American Druggist Syndicate held its third annual convention in New York September 9 to 11. The attendance of 3,000 represented every State and Territory except Alaska.

Obituary Notes.—Dr. Joseph A. Hodge of Henderson, Ky., died at his home on August 30, aged 79 years. Dr. Hodge was graduated from the medical department of Louisville University in 1850 and for forty years had practised his profession in Henderson. He served for two years as president of the State Medical Society and was a prominent member of other associations.

Dr. Lorenzo Hale of Albany, N. Y., died at home on August 31, in the sixty-fourth year of his age. Dr. Hale was a graduate of the Albany Medical College and for several years was editor of the *Albany Medical Annals*. He was also a member of the Albany Medical Society, of which he was at one time president.

Dr. Frederick H. Hooper of New Bedford, Mass., died on August 31, aged 78 years. Dr. Hooper was graduated from the College of Physicians and Surgeons of New York and began the practice of medicine in New Bedford in 1857, failing health causing his retirement about five years ago. He was a charter member of the Massachusetts Medical Society.

Dr. Charles Harrington of Boston died suddenly in London on September 11, aged 52 years. Dr. Harrington was born in Salem, Mass., July 29, 1856, was graduated from the Harvard Medical School in 1881, and pursued postgraduate courses in several of the German universities. From 1883 until quite recently he was a member of the teaching staff of the Harvard Medical School, and had held several positions as chemist and analyst under the Massachusetts State Board of Health.

LETTERS TO A NEUROLOGIST.

To which are appended brief replies purporting to set forth concisely the nature of the ailments therein described, with remarks on their appropriate treatment.

XII.—A Drunkard's Plight.

My dear Doctor.—I am seeking you as the highest court; I need your help and your sympathy. I am no craven, rather a blind bird battling for light. Forgive this outburst and I will be sane and state my case as I know it.

It is difficult to state the precise moment at which I awoke to a realization of a taint, a hereditary predisposition, a preordained infirmity, with which I had to cope, in addition to the other adversities of life. I am humiliated that I have not put up a better fight, but I have not yet despaired. With your help I may win out. Contrary to the Holy Writ, it is that which goeth into the mouth that has defiled me.

In my schooldays there was no craving for alcoholic stimulant: in fact, I was what is nowadays termed "a molly coddle." At my university I traveled with a rapid crowd, and perhaps "outheroded Herod," but the twelve years which intervened have dimmed the recollection of how firm a hold alcohol then had upon me. Drinking was always a lark in those days, not the means to an end, as it became later, nor the irresistible impulse it is now. After my graduation I spent two years in New York studying architecture. My experiences there confirmed me in my taste for alcohol, and six years abroad stamped deep in my constitution the craving for drink. But it is only during the past four or five years that it has absolutely enslaved me. In the beginning a small amount of alcohol would give me a brace—would wake my brain to greater effort, would broaden my field of vision—would almost dictate trains of thought, and so I used it, until one day I awoke to the fact that the dose had been increased enormously, that reaction followed the stimulation almost immediately, and that instead of being an aid to me in my work I was absolutely unable to finish anything. Now and then I have ideas, definite conceptions, and I think I will whip them into shape, but, alas, I don't succeed. I am now in the condition in which I would go to your office, deny my infirmity, and yet, if you chanced to leave the room, drink from a bottle of pure alcohol on the shelves of your dispensary.

I realize how necessary it is that I should abstain from alcohol, and countless times I have resolved to do so. I have fortified my resolution with prayer, by appeals to that Source from which we are promised that there shall be no denial if we go sincerely and humbly. How often have I read "Whatsoever ye shall ask in prayer, believing, ye shall receive," and how bitterly disappointed I have been that my appeals were always unheeded. I have strengthened my will by pledges to one whom I hold in higher regard than any one in the world; by physical discipline, and by counsel from your profession, I have sought refuge in the country, remote from centers where drink was to be obtained. I have availed myself of the sanity, the loyalty, and the devotion of my wife by sharing with her my fears and my determination to make a daily, an hourly fight against temptation. I have even taken the Keely cure! Yet all to no avail. The physician here says I am threatened with neuritis and acute Bright's disease, and tells me that I must stop alcohol. He neglects to tell me *how* I shall stop. I have no desire to disgrace my family

or to fill with misery and incapacity the years that remain to me. I am a man of sentiment and of education, possessed of a sense of duty to my family and to the community in which I live—and, delivered from this demon, it is possible that I might be able to do something that would contribute to the joy of living for others. But unless I can get aid I am through, and the sooner I experience translation the better for me and for all those whom my existence concerns.

It is not alone the fact that my capacity for work has gone, but I am enthralled, enslaved, emasculated by this monstrous hirudinean that has worked its way into my soul. This is the ignominy. There was a time when I awoke each morning with a joy of life, a desire to accomplish, a capacity to do, a feeling of well being, which, now that they are only memories, are to me as the sight of green meadows, winding rivers, and cool forests are to the traveler irretreviably lost in the desert. I can't conceive what sensations I was seeking which lead me to change all that for the feeling of self-disgust, of physical discomfort and moral turpitude which were soon the matudinal sequence of my nocturnal imbibition. I recall that in those days, coupled with the regret for my action of the day before, there was always the resolution that I would abstain for a long time. Occasionally I would be be able to go two or three days without recourse to drink, and then, despite my strongest effort, I would blot out every mental and moral resemblance to my Maker. Gradually there fell from me, like rags from a beggar, the desire or the willingness to abstain at all, and in its place came my present incessant craving. I see the necessity for work. I see it lie before me in various stages of incompletion; I realize the weighty obligations that are imposed upon me by my children. I am deeply conscious of the finger of contempt pointed at me by my fellow men; I have a sincere desire to live a life of usefulness and to accomplish something worth while. No one can realize more keenly than I do that I must deliver myself from this octopus which has fastened itself upon me, which has sapped my moral core and destroyed my will power. It availeth nothing to tell me that I must stop; as well tell water not to run down hill or sap not to well upward in the tree. Nor are any of the devices or admonitions which have been suggested to me adequate to combat it.

These words are not the wail that indicates recovery from a debauch, nor are they the lucubrations of a brain recently befuddled with alcohol. I have recently recovered from what is thought to have been a serious illness following a convulsive seizure, which the doctor tells me was of uremic origin, induced by drinking a bottle of vermouth—the only thing that I could lay my hands upon, and which I consumed practically in one sitting. I will do anything that you tell me to do, provided that you will give me serious and comprehensive attention.

It will not suffice to give me advice and a prescription. That has all been done before, and it has availed nothing. What I ask is a resuscitation from a state of death as real as that from which Lazarus rose. That required a miracle, and I am convinced that nothing less will suffice for me. I scarcely hope to be transported back to those days of my youth when a draught of water could slake the pleasant thirst of exercise or mollify the parched lips and tongue of the noonday heat, but I hope and pray that it may be vouchsafed me to enter once more with elation and exaltation into the pursuit of some self-selected task and the discharge of obvious duties, to have the capacity to think and to execute; to do something for others that would make the burden of their lives lighter and the cheer of their days deeper; to enter with alacrity and abandon into the pleasures of my children, and to be to my wife that which her fancy and belief pictured me twelve years ago.

As St. Monica, drawing near to her death, sent most pious thoughts as harbingers to heaven, and her soul saw a glimpse of happiness through the chinks of her sickness-broken body, I am sending this appeal to you to combine the offices of physician and friend and deliver me from an infirmity which, I say in all humility, makes life intolerable. It has reduced me to a state in which I can say, like the melancholy poet in the Northampton Asylum—

> "Where there is neither sense of life, nor joys
> But the huge shipwreck of my own esteem
> And all that's dear."

Yours faithfully,

Dear Sir.—I hope I shall be able to help you. Your appeal is one to which I am particularly sensitive. The task you set me is an onerous one; experience has taught me its difficulties. I need not tell you that inebriety, or habitual drunkenness, is a common disorder. The request to undertake the treatment of a case is no rare experience. The unusualness of the solicitation in this instance lies in the fact that it comes from the person who is concerned, not from the family, husband, parent, or wife. The afflicted person, as a rule, resents interference with what he calls his freedom, or the right to do as he pleases. This attitude often constitutes a barrier which must be broken down before anything can be accomplished. Fortunately, in your case you realize the necessity for extrication from the pit into which you have fallen, and you are willing to work with me. That will lighten the task somewhat and give greater promise of success.

The treatment of habitual drunkenness or inebriety is a concrete problem. There are no rules which, if followed in every instance, will result in success. In fact, you admit this in your letter when you say that a prescription and a regulation of your diet and your exercise will not be adequate. The successful treatment in any given case demands study of the individual, of his antecedents, of his disposition, of his habits of thought, of his ways, of his environment, of his methods of dealing with the situations of life, of his pleasures, of his appeals, and of his self-reliance. His amenability to suggestion, his capacity for obedience, his willingness to undergo humiliating experiences and self-effacement—all these, and more, must be determined. An intimate knowledge of the way in which the drink habit has fastened itself upon the individual is likewise very important for the physician. Whether or not it has been the outcome of conviviality or the clamoring of a sensation for appeasement. If it is a habit merely, and not a constitutional reaction, there is a chance of overcoming it more readily.

It must be difficult for the reader of current literature to realize that inebriety is the menace to the health and happiness of so many people as we physicians know it to be. A recent article in the *Century Magazine* by one of the directors of an institution connected with the Emmanuel Church, in Boston, which they are pleased to call a clinic, re-

ports that about 80 per cent. of the habitual drunkards upon which he has tried his 'prentice hand have been cured. In the August number of *McClure's Magazine* of this year, a professor of psychology of Harvard University says that it is his experience of the last few years, during which he has studied the effects of suggestion and hypnotism on habitual drunkards, that in most cases it is an easy matter to cure social drunkards of the larger cities. It seems incredible that there should be any real drunkards left when such wonderworkers are still at large, and when such master hands are still unshackled! Not being plain doctors of medicine, they do not feel obliged to give statistics in support of their statements, mere allegations sufficing. A physician who would report a cure of 75 per cent. of the cases of habitual drunkards treated, and give no statistics to support his claims, would find few readers and no believers. But let a man whose training has not been with such concrete matters as disease, one who deals largely in abstraction, make such statements, and they will be accepted by many who ought to know better.

Travelers who visit the Island of Martinique marvel at the temerity of the inhabitants of St. Pierre who take up their residence on the site of the city, which was wiped out by the eruption of Mt. Pelée. They build their houses on the lava that covers the bodies of their children, their wives, and their parents. Every few years the Ohio River at certain places along its course overflows its banks and destroys property and human life. The inhabitants who escape build their dwellings again on the banks of the river after the stream has receded, and take up life anew, forgetting, or unheedful of, the potential danger. The attitude of the people of this country in reference to the cure of alcoholism is very much like the attitude of these seemingly hazardous people.

It is scarcely fifteen years since the press of this country teemed with laudatory articles on a certain cure for alcoholism. Senators, divines, men eminent in law and in the councils of the State, vied with each other in setting forth, through the medium of our most dignified magazines, the marvelous cures which, to their personal knowledge, had been effected by this secret method of treatment. Institutions for carrying out the treatment sprung up throughout the entire country, and the number of cases treated successfully extended into the thousands and tens of thousands. Such appearance of verity did the cures have, and such justification for the existence of the method of treatment was furnished by responsible and important persons, that it was considered almost questionable taste to deny the validity of one or the efficacy of the other. Yet, who hears of this cure to-day? What has it accomplished? Is not habitual inebriety as great a stain on twentieth century civilization as it was a generation ago? Must we again offer the broad avenue of credulity on which irresponsible drivers of fads and fancies may promenade and display their wares, or shall we have the courage of our convictions and deny their assertions, scoff at their statements, and treat with indifference their excursions afield from their own profession?

It is unfortunate that each country or section of country is not in possession of an island which might be set apart for the reception of habitual drunkards, to which they could be sent by process of law for a number of months or years, depending upon the intensity of their affliction. A fertile soil would provide sustenance and a strict system of quarantine would keep out alcohol. If the place should get a vogue as a favorite resort of some of our "first" families, and this might be easily brought about, people would go to it not only willingly, but with alacrity. Victims of the drink habit are proverbially attractive persons, and a community of them would be almost irresistible. You may find the scheme too Utopian, or at least too far remote from realization. Let me advise something more practical. My suggestion is that you commit yourself voluntarily to an institution where you can be deprived of your liberty for a year. If you are not willing to do this, go to a training school, such as ....., and stay there a few months, and at the end of that time engage a trainer to accompany you to your home, and empower him with authority to keep you from taking a drink. Do as I suggest about making voluntary commitment of your person, and at the end of a few months you will begin to get strong physically and well balanced mentally. Work will once more appeal to you, and the joy of creating will begin to dawn upon you again.

If you will not do this, then you might send for the elders of the town, who will say, "This, our son, is stubborn and rebellious; he will not obey; he is a glutton and a drunkard," and then ask them to stone you with stones until you are dead, as the stubborn son was treated by the people of Israel.

I am not saying very much to you about using your will power. I appreciate that your will power is pretty well lost. It will redevelop and establish itself in proportion as you refrain from alcohol. The time to talk to you about will power is after you have abstained for a few months. You should then receive treatment by suggestion, and the person from whom it may come most appropriately—for he is with you all the time, and in a position of authority—is the trainer. You will note that I am using the word trainer to mean one whose duty is to develop you physically, mentally, and morally, and to superintend you. I wish to digress a moment at this point, to say that we are badly in need of a new profession, the training profession. We need trainers to develop children who suffer from mental retardation, to treat the victims of psychasthenia, to foster the waning intellectual powers of patients with dementia præcox, to curb the impulses of the obsessed, and to develop self-reliance in the alcoholic.

The profession of trainer is entirely distinct from that of the nurse or doctor, although occasionally a good trainer may be recruited from the ranks of either of these professions.

It may be that you prefer to get your suggestion from beneath the cloth, now that so many clergymen are construing their duty to be the treatment of disease as well as the preparation of mortals for the life hereafter. Their favorite suggestions are that the Lord will no longer single you out to bear humiliation and suffering; He did not intend that you, made in His image, should be committed to torture and despair; that He is appeased with the amount of pain you have already borne; that the desire for drinking will disappear; the uncontrolable impulse will not return; that if you will but think intently enough to get wholly *en rapport* with the Lord the impulse to offend will not take its origin within you. If you are fortunate enough to have faith to believe that there is a personal God who watches over you, that the very hairs of your head are all numbered, who is conscious of your every thought, and who will reward your virtues

and punish your sins, then this sort of treatment may be beneficial to you; indeed, it may cure you. If you can find it in your makeup to believe that ministers of the Lord are able to cure disease by virtue of the irradiations from God through them, then it is probable that you can get more help from a clergyman than you can from a doctor.

If you have what they call faith—that is, "assurance of things hoped for, a conviction of things not seen"—if you have within you an assurance that the desire for alcoholic stimulant will leave you, and a conviction that there is a Power looking after you who will keep it away if you will ask with sufficient humility, then you are cured, and you are not called upon to go to Boston, which will be a second reason for rejoicing. If you have the kind of faith which the Lord said the Apostles should have when they besought Him to increase their faith and He answered, "If you had faith as a grain of mustard seed, then ye might say unto this sycamine tree, Be thou plucked up by the root, and be thou planted in the sea, and it should obey you"—but if you haven't got this variety there isn't much hope for you in that direction.

These Christian Scientists in Boston, who are masquerading under an assumed name, and who do not hesitate to call their Reverend Mother's religion a "despicable superstition," are animated primarily by desire to regenerate the Christian Church. They think their movement is an answer to the materialism of the age which threatens the church with extinction. They believe that Christ's mission was that of a physician, a healer of the souls and bodies of men, and that they should take up the practice as a sort of limited liability company. They balk at organic diseases, the kind that Christ cured so readily. What they are pleased to call functional disease is the grist they grind.

And the answer they give to those who ask with all reverence why God should discriminate between functional and organic (a mere makeshift of ignorant, benighted man) is the same as that given by M. de Mongeron, the pious biographer of François de Pâris, a miracle worker of the sixteenth century, to the Bishop of Sens, who, on being shown a boy whose blindness had been miraculously cured in one eye, ventured to inquire why the Lord didn't cure them both—"We haven't the right to question the ways of the Lord."

Granted that Christ was a physician. He was not a specialist in functional disease. "The blind receive their sight, and the lame walk, the lepers are cleansed, and the deaf hear, the dead are raised up, and the poor have the Gospel preached to them." Nor are His instructions to His Apostles any less comprehensive, "Heal the sick, cleanse the lepers, raise the dead, cast out devils." Those were the orders, and if the successors of the Apostles aspire and are ambitious to do the one, they should do all.

To students of the Bible like myself (shortly I shall be interpreting my mission as a physician as a call to preach the Gospel, so contagious is this vicarious assumption of function), Jesus is the best authority as to His mission. "The Spirit of the Lord is upon me, because He had anointed me to preach the Gospel to the poor: He had sent me to heal the brokenhearted, preach deliverance to His captives, and recovering of sight to the blind, to set at Liberty them that are bruised. To preach the acceptable year of the Lord." I should point out to you that this is taken from that portion of the Holy Writ which was furnished by one who is not entirely reliable, a physician, Luke, who may have been jealous of the Lord. At least, this suspicion has been thrust into my mind by the Reverend E. Worcester, who says in "Religion and Medicine," page 344, "Luke, being a physician, could not tolerate any reflections on the medical profession."

If these divine healers do what some of them claim to do in the field of disease, and assume that it is done through their mediation of supernatural agencies, there is no reason that they should not bind and loosen upon earth as well. Their claims to do so would be no less arrogant than their therapeutic pretence.

I am not using this opportunity to scoff at a profession which is deserving of the glory and honor universally accorded it. I utilize this occasion to say that it is not frank, or honest, or honorable, to ascribe to supernatural agencies or to the intervention of God, the operation of psychological and physiological processes susceptible of scientific and empiric explanation. One may believe, if it comforts or promotes respect and reverence, that when leaves fall from a tree a supernatural force causes them to fall, but the wind that is blowing is nevertheless the logical and adequate cause.

There exists a vast mass of trustworthy material testifying to the reality of cures effected by other than physical means. No one denies it. These cures are susceptible to logical explanation. Does any one doubt the reality of the cures effected by the Perkins-Tractors, or the King's Touch, or the Berkely Tar Water, or the hundred other agencies which have had great vogue in past times? Were they effected by God? The Emmanuel Church will have to quicken its pace to get as many real cures to its credit as Mr. Perkins had before he was gathered.

Unless the Emmanuelites believe as the Reverend Mamma of Brookline believes, that sickness is sin, they haven't a leg to stand upon. When Jesus was leaving Capernaum a man sick of the palsy lying on a bed was brought to Him as he entered the ship. He said to him, "Son, give good cheer, thy sins be forgiven thee. Arise, take up thy bed and go into thine house." The real Christian Scientists are much more logical than those who ape their tactics so closely that it is difficult to distinguish them, but who are ashamed to fight under the flag.

I say to you if you need supernatural aid go to the chief pumping station; go to Boston, of course, for Boston is the irradiating center for all forms of supernaturalism, but when you go, go to the Temple, not to the Church. If, however, you are a philosopher, and believe that the way to rid yourself of an infirmity that is the legitimate sequence of a bad habit is to replace it by a good habit, and the way to overcome an impulse which is dependent upon enfeebled will power is to develop will power in some systematic way, as you would develop memory or muscle, then I advise you to pin your faith to the profession that practises the cure of disease legitimately.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

ARMY MEDICAL REPORT—DUSTY TRADES IN RELATION TO PULMONARY DISEASES—ANTITYPHOID INOCULATION FOR MISSIONARIES—DEPOPULATION OF IRELAND—FOOD INSPECTION—OBITUARY.

LONDON, Aug. 28, 1908.

THE report of the Medical Department of the Army for 1907 has appeared and shows that the health of the troops both at home and abroad was exceptionally good. Since 1904 the introduction of the out-patient system for mild cases has diminished the rate of hospital ad-

missions, but the decline in mortality and invaliding rate may be accepted as an indication of improvement. In India, South Africa and Egypt the reduced sickness is apparent, but there was an increase in Gibraltar. The figures for India show remarkable progress, the admission and death rates being the lowest on record. The Director-General draws special attention to the returns under the head of venereal diseases, which long caused an enormous amount of inefficiency. In 1897 the hospital admission ratio was 507.8 per 1,000; in 1907 it fell to 89.9, a result to which several causes may have contributed, but which is certainly very satisfactory. As regards invaliding in India, during the last cold season the experiment was tried of sending weakly men to selected hill stations in the country, instead of to England. The result was most satisfactory, the men improved in a marked degree. These hill stations have an unrivaled climate in the winter. A decrease of 1,008 invalids is reported as due to this new departure. The retention of over 1,000 trained and seasoned soldiers is an important gain.

Another noticeable gain appears in the decline of sickness in Malta. Perhaps no better example can be quoted of the success of scientific prophylaxis than the history of fever among our troops on that island. The returns show that the hospital admissions for Malta fever in 1905 numbered 643, in 1906 they were 161, while in 1907 they were only 11. The number of invalids sent to England from this station decreased from 383 in 1905 and 165 in 1906 to 14 in 1907, while the average number of those rendered constantly inefficient from Malta fever dwindled from 111 in 1905 and 43 in 1906 to only 3 in 1907. Further instances of the successful application of sanitary and prophylactic measures, though to a much smaller extent, are reported from India, South Africa, Egypt, and the Straits Settlements. To deal with typhoid a standing committee has been formed in India, while in South Africa important investigations are being carried out. Differences in bacteriological characteristics are reported as having been found between enteric fever as prevalent in these two countries. Tables are given showing the general state of health of British and other armies, from which it appears that the only armies showing a reduced rate in comparison with the previous year of hospital admissions are those of the United States and of Great Britain. But you must not plume yourself on this fact and must note that it is in comparison with the previous year only that you come out so well, for further tables show that in respect of all diseases the United States Army heads the list with the highest ratio, followed by that of Austria-Hungary, France, Germany, Russia, and Great Britain, in the order named. The death ratio for all diseases in the six armies remains at about the same relative position as in the previous year.

It was only appropriate that at the Sheffield meeting a whole morning should be given up to the discussion of dusty trades in relation to consumption and lung diseases. Dr. Scurfield, the able Medical Officer of Health, introduced the subject. He pointed out that while in England of people over 25 years three males to two females died from consumption, in Sheffield the proportion was six males to two females. This meant that about 120 men a year died in Sheffield who need not die if the conditions of work were as good as in the rest of the country. Other figures showed that bronchitis and pneumonia prevailed among the workmen of the dusty trades. Through the trades unions he had been able to get some important statistics. They showed that the death rate of the grinders from phthisis was more than six times and from respiratory diseases nearly three times that of the average Sheffield male. In the case of cutlers the phthisis rate was nearly three times and the rate of respiratory diseases four times that of the average male.

Dr. Scurfield quoted the investigations of Dr. Ropke of Solingen, who considered all dust made by grinders injurious, particularly stone, emery, and iron dust. The effect of the inhalation was on the nasal mucous membrane, which eventually atrophied and was followed by a like injury and the same result in the pharynx and larynx. This facilitated the access of the dust into the lungs and the formation of dust-filled fibrous inflammatory masses, which on breaking down gave an open door to bacilli. Dr. Scurfield mentioned that it was a common belief in Sheffield that animal dusts (bone, horn, ivory) are harmless. Even if that were so they would be carriers of bacilli. The Germans in 1898 laid down stringent regulations to secure cleanliness in workshops and prevent the inhalation of dust by the workmen, and they claim to have thereby enormously reduced the death rate. Sheffield certainly offers abundant room for a similar effort.

Professor Oliver said the relation between the male and female mortality left no doubt as to the influence of the trades, and the same thing was going on in America, though not to so great an extent. There was no doubt that some dust—for instance, coal dust—could be present in the lungs for a long time without setting up symptoms. On the other hand, dust of an irritating kind would set up active inflammation. Professor Oliver added that he had been struck with the poor, thin arms of the young workers at Sheffield, whereas one would expect the muscles to be developed by their use. He would like an explanation.

Dr. Barnes of Sheffield said the grinders' disease was pure tuberculosis, and Dr. Dyson of the Infirmary had authorized him to state that this opinion had been enforced on him also. He had gone through notes of fifty cases investigated by Dr. Cocking and forty-nine were pure phthisis. Colliers and sulphur miners inhaled dust, but were not subject to phthisis. The source of infection, Dr. Barnes continued, was the sputum of the grinders. In dry-grinding shops they spat on the floor, in wet grinding shops into the troughs, and the bacilli were caught by the revolving wheel. He would make it punishable to spit on the floor. The regulation against spitting in public was insufficient at Sheffield, as seen by the state of the tops of the tram cars.

Dr. Nevin thought the particles of dust made way for the bacilli and men with damaged lungs would be susceptible to slight infection, so that to banish the bacilli from the workshop would not eradicate all risk.

Dr. Kite said in his district some years ago ganister disease was the most prevalent form. It was due to silica in the air and was very fatal. Once he had eight or nine hundred cases, but it had now practically disappeared. The British workingman had to be protected against himself. In one factory the greatest difficulty had been found in getting the men to take precautions against anthrax. In reference to Professor Oliver's remark, he said the thin arms of Sheffield children were due to want of fresh air and exercise.

Dr. Ellis Barker said the better conditions in Germany were due to the system of insurance, which made masters and men jointly interested in maintaining them. When England does this her difficulty as to sanitation will vanish.

Dr. Woodcock of Leeds spoke of contracting the disease in houses. He also said that in Leeds the mortality of Jews was excessive. They were mostly tailors and he supposed it would be said they worked amidst infected dust.

Dr. Scurfield, in the course of his reply, said that phthisis among women in Sheffield was less than in most other towns and yet there was this enormous amount among the grinders, who did not pass it on to their wives, but did to their fellow workmen. If dust was not the cause, what was?

Medical men connected with or interested in missionary societies have of late recommended antityphoid inoculation to those about to engage in mission work where the fever is more or less endemic. The matter has been laid before those concernd by Dr. Hingston Fox, who has contributed an interesting paper on it to the *Journal of Tropical Medicine*. He shows that missionaries are more subject to typhoid than even soldiers. Of sixty-three stationed in Central India eleven were attacked by enteric fever, of whom one died and two were compelled to give up mission work. In Madagascar seven cases occurred among fifty-three missionaries, one fatal. Dr. Fox says that Sir A. Wright's inoculation reduces the liability to contract the disease by about one-third. He describes the preparation and standardization of the vaccine and the mode of inoculation with other details, for which those interested are referred to the journal above quoted for last month.

A further decrease in the population of Ireland is reported for 1907, though there was an excess of births over deaths of 24,408. The loss by emigration amounted to 39,082, which is above the average of the ten previous years. The deaths equaled 17.7 per 1,000, which is 0.2 under the average. There was no death from rabies, the country having been free from that since 1898, when four deaths were returned as due to it. Deaths from the effects of alcohol show an increase. Excessive mortality from tuberculosis is again reported, although it may be hoped that the inauguration by the Countess of Aberdeen of a Women's Health Association for Ireland and the tuberculosis exhibition held in Dublin will show some effects in the next report.

The Local Government Board issues this week a circular on food inspection. The value of our food imports exceeds £200,000,000 and the instructions and advice to local authorities concern more than half. It is expected that the effect will be to secure the purity of the food of the people. The investigations on which it is founded were undertaken in consequence of a "scare" two years ago.

Thomas Orme Dudfield, M.D., St. Andrews, died on the 30th of July, aged 75. He was for many years Medical Officer of Health for Kensington and took a most active part in all matters relating to sanitation and local government. He was a past president of the Society of Medical Officers and he represented them on many occasions to the local and general government. On all questions of medical politics he was an able and thoughtful authority.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 3, 1908.

Deceptive Conditions in the Hip-Joint.—Histories of five cases are given by R. Hammond, who says that a diagnosis based on clinical signs and symptoms alone will not always be an accurate one. Of the cases reported, the first illustrates a tuberculosis of the hip following fracture of the femoral shaft, the picture being completed by the result of the *x*-ray examination and the tuberculin test. In a second case tuberculosis of the hip followed a fall. A diagnosis of fracture of the femoral neck was suspected, but none found. In a third case hip disease was suspected, but the radiograph showed an old fracture of the femoral neck. In the fourth case osteomyelitis was found just below the great trochanter. In the fifth case there was a traumatic separation of the epiphysis of the upper end of the femur which from the history and symptoms might have been confused with tuberculosis except for the use of the *x*-ray, and the tuberculin test. The author adds that tumors involving the bone, both benign and malignant, in the early stages are frequently confused with tuberculosis and all the methods of diagnostic precision which we possess often fail of an accurate diagnosis. This is especially true in the case of benign bony tumors and bone cysts, which often present the greatest difficulty in correct interpretation.

Erythema Multiforme with Visceral Lesions.—J. N. Hall refers to Osler's collation of cases of this association, and adds two personal observations. In his first case, that of a male of 23 years, who, in addition to his dermatosis, presented evidences of a parenchymatous degeneration of the kidneys, with colicky paroxysmal pain at the epigastrium similar to that seen in locomotor ataxia, gallstone disease, gastric ulcer, appendicitis, etc., but under treatment directed to the dermatosis all the abdominal symptoms cleared up. In his second case, a male of 29 years, the dermatosis came on after eating strawberries not quite ripe. Considerable edema existed about the wrists for one or two days. A single ecchymosis was present under the mucous membrane of both upper and lower lips. Sharp nose bleed occurred. Severe arthralgic pains caused much complaint. The temperature rose as high as 103.8 degrees, declining gradually to normal on the tenth day. The pulse varied from 80 to 120. The patient was semicomatose during the first two or three days, awakening to complain of frightful headache and photophobia. The neck was retracted, there was stiffness in the muscles of the back, and knee jerks were exaggerated, and an imperfect Kernig's sign was stated to have been present. Very marked hyperesthesia existed over the face and neck so that the lightest touch was painful. The Widal reaction was negative and the spleen was not enlarged. The heart was negative. On the fourth day a spinal puncture was made with rather unsatisfactory findings, but on the sixth day perfectly clear fluid was obtained containing no microscopic evidence of meningitis. Flexner's serum for cerebrospinal meningitis had been sent for, but was not used. After the spinal punctures the comatose condition cleared up, but the headache persisted. The urine was negative throughout; no gastric or intestinal symptoms appeared. By the tenth day the fever had practically subsided. Recovery was uneventful.

New York Medical Journal, September 5, 1908.

Carsickness.—W. C. Wood attributes carsickness to the nystagmus produced by looking out of the car windows. Look out of a car window and observe how rapidly the telegraph poles flit by; each one is seen and involuntarily followed by the eye until it is opposite, when the eye shifts to the one following. This is true of near buildings; objects farther away seem to move slower, and those very far off seem to be almost stationary, until the whole landscape appears to be revolving round a common center. The unconscious effort to take in everything produces a rapid lateral oscillation of the eyeballs, as any one can observe by watching the eyes of his fellow passengers. The eye strain is enormous, and is the chief factor in producing carsickness. This can be proved by asking a patient who is subject to carsickness to look steadily at a mirror which is moved rapidly to and fro or tilted backward and forward. He will immediately complain of nausea and vertigo. The treatment consists in advising the patient to avoid looking out of the car windows and in giving him a grain of citrated caffeine shortly before he takes the cars, and repeating it every hour as long as there is any tendency to be sick. The author has been enabled by this procedure to relieve many sufferers from carsickness.

Preliminary Report on the Effect of Repeated Injections of Tuberculin on Lymphatic Organs.—This report is made by S. G. Dixon, A. J. Smith and H. Fox, who say that the condition of the spleen in guinea pigs after treatment with tuberculin or some producer of the tubercle bacillus like it suggested that this organ might be the seat of some pathological change after injection of these solutions. The question actually arose whether the inexplicable deaths among cattle after testing might not in some way be connected with this substance. In the course of their work in this laboratory they have repeatedly encountered focal necroses in the spleen, and occasionally in the liver of guinea pigs and rabbits dying of the injections of the various tuberculins. These necroses were suggested by the naked eye appearance. The lymph nodes were not attacked by these areas, even those in close proximity to the point of inoculation. The foci of necroses were not sharply outlined, but usually were surrounded by large lymph cells or endothelium. Around the older ones was sometimes a zone of polynuclears and round cells, rather indicating a throwing off of the necrotic remains. The endothelium was almost always slightly hyperplastic. In order to see if severe treatment of a healthy cow with tuberculin would produce anything similar to this an animal was injected six times, two weeks apart, with 400 milligrammes of old tuberculin under the skin. She did not react at any time. She was killed two weeks after the last dose and at autopsy appeared to the naked eye to be a healthy animal. The pathological histology of spleen, lymph glands and liver is described in full. The prescribed treatment in this animal did not produce any distinct focal necroses. There was, however, a tendency to hyperplasia of the endothelium which went on to vacuolization and necrosis. This was more diffuse than usually seen in guinea pigs' spleen and affected frequently the sinus and endothelium. Although the endothelium has suffered in both the guinea pigs and the cow, no hemorrhages were present either great or small, thus speaking against any lytic change. The phagocytosis and pigmentation rather lead the authors to attribute the degeneration to great proliferation incident to the toxemia.

Tuberculin an Adjunct to the Home Treatment of Pulmonary Tuberculosis.—J. A. Miller reports on 46 patients whose treatment was continued for a period of six months. Some were treated in their homes and some at various clinics and hospitals. Three main principles guided him in the selection of cases: (1) No early or favorable cases for whom sanatorium or other climatic treatment was available were kept in New York. (2) No cases with fever were treated, with two exceptions. (3) Tuberculin treatment was urged only for patients who were not progressing favorably without it. As a result of these three principles the patients treated have been largely long-standing advanced cases, who were gradually drifting into more or less chronic invalidism. The author then takes up successively the questions of varieties of tuberculin used, dosage, guide to dosage, etc. In the forty-six patients under consideration, the following results have been obtained: Four patients (8.7 per cent.) were apparently cured; in eleven patients (23.9 per cent.) the disease was arrested; nine patients (19.6 per cent.) were improved; eleven patients (23.9 per cent.) were stationary; eleven patients (23.9 per cent.) were progressive. As far as statistics go it would seem that any form of treatment must have considerable efficacy which is able to show the improvement in condition, with such a degree of permanency in such a class of cases, and under such conditions as are here reported. As to clinical impressions, his experience has included several patients in whom the results of the tuberculin appeared truly remarkable, in some others there has been distinct disappointment especially in a few which seemed at first to do exceedingly well, and then relapsed later, just as is customary in tuberculosis, but which we would hope not to find when any degree of immunity had been established. It cannot be too strongly emphasized that if good results are to be obtained by therapeutic use of tuberculin, the

greatest patience and care must be exercised in every particular. The dilutions should be made only by some one who is skilled in such work. Any evidence of intolerance must be carefully noticed, and the progression of dosage correspondingly regulated; and lastly and perhaps most important the duration of treatment must be extended over a very considerable time, preferably from six months to a year.

Journal of the American Medical Association, September 5, 1908.

Esophageal Surgery.—N. W. Green and J. W. D. Maury tell their experiences in the experimental surgery of the esophagus and illustrate the apparatus employed. They operated in two ways. In one the esophagus was sectioned, reuniting the proximal end with the cardia of the stomach; in the other, there was a side tracking of the cardiac orifice similar to the method of Biondi, using during these procedures an apparatus for artificial respiration using positive pressure, which is described in the *Annals of Surgery*, October, 1907. The sectioning was done with the aid of sutures and the Murphy button which has the merit of making a continuous tight joint. Their experience leads them to believe that a mechanical device that makes an anastomosis with absolutely no soiling of the serous membrane, forming also a tight joint, will prove of the greatest value in preventing infection. Dead spaces in the chest should be overcome as much as possible at the termination of the operation by increased air pressure. They speak of the absence of omentum with its coapting power as a disadvantage, and in one instance they have carried omentum into the chest and applied it to the wound. The constant motion of the diaphragm may interfere with proper union, and they have stretched it on the operated side and interrupted the function of the phrenic nerve in an effort to overcome this factor. They describe in detail one method of operating which has been very satisfactory in their hands.

Recumbency in Convalescence.—C. C. Frederick advocates keeping patients in bed after abdominal operations for a longer time than is now advised by many operators. With the exception of appendectomies, not acute, he would say that no patient after abdominal section ought to be allowed to be up before the lapse of from sixteen to eighteen days. The reasons he gives are the incompleteness of union before that time with the consequent greater risk of hernia, and the need of such a period of rest in the usually debilitated state of the patient. Since following this rule he has not had 1 per cent. of hernia in his abdominal cases, and, while the use of the buried suture has contributed, he lays this success largely to the longer recumbency. Of course, in a person operated on in full vigorous health the second reason does not apply to the same extent, but the danger of hernia is still present.

Surgery of the Thorax.—E. F. Sauerbruch describes his device of a pneumatic cabinet to avoid the danger of pneumothorax in operations on the thoracic organs and the rules to be followed in its use. It is remarkable, he says, how little of the anesthetic is required and then only at the times of opening and closing the thoracic cavity. Between these very little is needed. It has been found unwise to reduce the pressure more than from 7 to 8 mm. Hg, and Friedrich has had excellent results with a negative pressure of from 3 to 5 mm.; in fact, such a minimum pressure should always be employed during intrathoracic operations, as on the esophagus or lungs, or when it becomes necessary to expose the mediastinum. Before concluding the operation, however, it is essential to raise the pressure to 7 or 8 mm. so that the lungs will be fully expanded and completely fill the chest cavity. The strictest asepsis is as important as in abdominal operations, and complete hemostasis is of the utmost importance so that as little blood as possible enters the thoracic cavity. As regards the indications for this method, he says that it is particularly applicable for the removal of large tumors of the chest wall, lessening the dangers and rendering it possible to operate more extensively, and the contraindications are fewer. If, in spite of care, the pleura is injured, the apparatus will prevent the occurrence of pneumothorax. Its possibilities in the treatment of pulmonary tuberculosis will increase, but too much must not be expected; in fact, he believes that in such cases thoracoplastic operations will give better results. Excellent results have been obtained with the method in empyema, and it has great advantages in the surgery of deep abscess and gangrene of the lung. Changes of dressings, it has been shown by experience, should be made in these cases, at least in the beginning of the after-treatment, under negative pressure, not because of pneumothorax, but solely because it tends to remove blood and pus from the bronchi. In bronchiectasis it is applicable only when the lesion is isolated in one lobe of the lung. The method is useful in operating for intrapleural injuries, and it is especially indicated in operations on the intrathoracic portion of the esophagus, and Sauerbruch has developed a technic which makes it possible, at least in animals, to resect large portions of the esophagus. The essential feature is the avoidance of sutures and the use of the Murphy button for the anastomosis. Gastroesophageal anastomoses and resection of the cardia have been performed on man. The operation is described. The surgery of the heart is the least advanced of this new method of using negative pressure, as heart injuries are always emergency cases. In closing, Sauerbruch speaks of the value of exploratory thoracotomy in clearing up doubtful diagnoses, which he considers more often justifiable than has been thought to be the case.

Serum Diagnosis of Syphilis.—W. J. Butler gives the history and describes the complement fixation test of Wassermann and reviews the literature of the serum diagnosis of syphilis. He holds that the large proportion of positive results in luetic and suspected luetic cases, and the uniformly negative results in controls, indicate the specificity and reliability of the Wassermann test. Butler has used the test in 125 cases, but in 20 of these syphilis could reasonably be excluded, all of which reacted negatively. The other 105 are grouped under two heads, with subdivisions: 1. Cases of manifest or suspected syphilis and cases with a syphilitic history. 2. Cases with lesions of the nervous or cardiovascular system in which syphilis was neither acknowledged, denied, suspected or unsuspected. In the first division there were 61 cases: 4 in the primary stage, all positive; 25 in the secondary stage, 24 positive, 1 negative; 17 in the tertiary stages, 16 positive, 1 negative. Of latent cases, there were 15; 8 positive, 7 negative. In the second division there were 44 cases; positive reaction in 75 per cent. Of these, 40 per cent. had either no knowledge of infection or denied it. Butler summarizes his conclusions as follows: The serum reaction for syphilis is specific. It is found positive in from 90 per cent. to 95 per cent. of all cases with syphilitic manifestations. It is found positive in 50 to 60 per cent. of latent cases. It is found positive in from 70 to 80 per cent. of metasyphilitic and parasyphilitic diseases. In many cases the reaction is influenced by treatment of the patient, and it is not improbable that this number would be greatly increased if the reaction were pursued throughout prolonged treatment. A positive reaction indicates activity of the specific virus, and is an indication for specific treatment. While a positive reaction indicates syphilis, a negative reaction does not have an equal negative value. Its failure does not warrant any judgment as to cure. It is diagnostic simply of a systemic infection, whether this be acquired or inherited. The reaction will be found of enormous advantage in the determination of a differential diagnosis in every department of medicine.

Causes of Edema.—Martin H. Fischer discusses the nature and cause of edema. The cause, he asserts, resides in the tissues. The tissues become edematous, not because water is forced into them, but because they absorb water from liquids flowing through or about them. He relates in detail his experiments with frogs. In regard to the character of the tissue change, he states that it is clearly shown by these experiments that the severest grades of edema may exist without the presence of any "blood pressure" or a demonstrated "increased permeability of blood vessel walls." Edema, he believes, represents nothing but an increased affinity of the tissue colloids for water. If this theory be true, he declares that it must be possible to prove three things: First, that protoplasm is colloidal in substance; second, that in the variable affinity of colloids for water we have a force of sufficient magnitude to account for the maximum amount of water ever found absorbed by tissues in a state of edema; third, that conditions leading to an increased affinity of their colloids for water exist in the tissues under circumstances associated with the development of an edema. He briefly considers each of these possibilities and in regard to substances which increase the affinity of the tissues for water, he states that, with the exception of alkalies, acids, including carbon dioxid, are the most powerful substances known for increasing this affinity. And it is either the retention or production of acids in the tissues as rendered possible in conditions leading to an edema that he sees the chief cause for its development. He directs attention to the fact that dead bodies kept in water become edematous and states that this is because after death the tissues become acid and absorb water from their surrounding medium. For the same reason, gangrenous tissue swells if a source of water be furnished either from without or through the lymph or blood vessels. This conception of edema, he asserts, holds good for local as well as for generalized edemas. He cites glaucoma as a form of local edema and also the imbibition of water by the crystalline lens.

British Medical Journal, August 22 and 29, 1908.

A Third Report on Clinical Experiences with Spinal Analgesia.—Arthur E. Barker makes this third report with a third series of one hundred cases. A study of these three hundred cases appears to possess a certain value, although it would seem premature to adopt any decisive attitude towards this comparatively new procedure. It is still *sub judice*, and must long remain so. In this last series of one hundred cases there was a larger number of very serious abdominal operations, among them several enterectomies—one removal of the splenic flexure of the colon for cancer, one abdominal hysterectomy and pyosalpinx in the same case and at the same sitting, one ectopic gestation, etc. But throughout from time to time cases have been noted in which marked pallor came on soon after the injection, though there were no fatal results from it. Faintness has been followed usually by slight retching, and then a rapid return to comfort. There was no fatality among the three hundred cases due to the spinal analgesia. He regards the procedure as not without serious risk in debilitated patients where the upper part of the abdomen has to be dealt with. This is far from being the case. It was a remarkable fact that several cases had been in a very perilous condition of asthenia before operation, and have taken no harm from the spinal analgesia, while showing in their subsequent recovery an absence of those troubles from shock, vomiting, etc., so often seen after chloroform. From his own experience he says he is inclined to advise beginners not to use the method in extremely debilitated patients for severe operations on the abdomen requiring high analgesia. Their best results had been in operations below the umbilicus, and best of all on the pelvic organs.

Some Lessons from Ancient Fractures.—Frederic Wood Jones reports on a collection of two hundred cases of bones that have been broken in ancient times and have healed. These fractures were collected from a series of upwards of six thousand bodies buried in the Nubia that lies between Sheilal and Demhid and they are from representatives of all periods between the early predynastic times (the earliest period from which human remains have come down to us, *circa* 4000 B. C.) and the Christian era, until about the fifth century after Christ. They therefore cover a period of history of the human race of considerably over four thousand years. The most striking difference is seen in the figures relating to the fractures of the patella, and of the tibia and fibula. All fractures below the knee were very rare. The reason probably is that these people went barefooted, and lived at a time when there were no stairs, curbstones, or pavements. Fractures of the foot probably owed their rarity to the fact that wheeled traffic was absent. The two fractures that were notably more common in ancient Nubia were those of the forearm and of the clavicle. This was probably due to the use of the "naboot," a long stick, the Nubian's constant companion. The results of union of bone shown in their series are quite as good as those obtained by the surgical treatment of to-day.

Hyperpyrexia.—James Smith reports the case of a woman, twenty years old, who gave a clinical picture striking and suggestive. Commencing with a septic throat, followed after a short interval (during convalescence) by acute rheumatism, and culminating in extreme pyrexia (108.6° F.) and convulsions. It seemed probable that more than one toxin was active and contributory.

Rectal Injection of Bromides in Puerperal Eclampsia.—F. J. Jones reports the successful use of this remedy in the case of a primipara of 21 years. Just as the presenting part (breech) was born the first convulsion occurred. Chloroform was immediately given and the labor hurried to completion. A second convulsion occurred soon after and in spite of morphine by hypodermic use and bromides by the mouth, a third in about twelve hours. She was getting stupid and could not take medicine by the mouth. So the reporter washed the bowel out, gave half a dram of bromide with ten minims of belladonna tincture by rectum. No more convulsions occurred. The urine was loaded with albumin. Recovery was uneventful.

Bilharziosis of the Gastric Mucous Membrane.—The specimen referred to by A. W. May was from the stomach of a Chinaman. The naked eye appearance was that of a small pedunculated cystic growth about the size of a small bean, covered by the gastric mucosa. On section a distinct cystic condition and a small amount of a greenish-yellow fluid with a distinct butyric odor were seen. Microscopical examination of this fluid showed the presence of considerable numbers of terminal-spiked ova, typical in every respect, except that the spines had the appearance of being rather shorter than those found in other situations. Sections examined microscopically showed the tumor to consist of an outer covering of mucous membrane, with a distinct connective tissue capsule lining the cyst cavity. No ova were embedded in either of these structures.

Treatment of Bubonic Plague.—B. L. Paton observes that there are doubtless many cases of this disease in which treatment has been successful, though one very seldom sees reports of such cases. His own plan is to give one grain of carbolic acid in pill or mixture, every hour, and to inject the bubo with a varying quantity of the same drug in proportion to its size. From 2 to 15 mm. is about the range as to amount used. Several epitomized clinical histories are given. The author says that in his successful cases the gland or glands affected have always been *below* Poupart's ligament. It is important to keep an eye on the urine when carbolic acid is prescribed in such large amounts, as it is quite possible that some cases have died of the treatment where this precaution has not been attended to. As long as there is a free flow of urine of normal color the treatment is not doing any harm.

Treatment of Chronic Empyema by Hyperemia and Hypertransudation.—According to J. S. Dick there is a practical consensus of opinion that drainage adequate to the size and position of the opening and the length of time it is maintained, is the first condition of cure. He relates the history of a case of empyema following pneumonia. Two years from the onset of the latter disease and nine months from the first operation for drainage, there still existed a cavity with a capacity of over two drams and secreting one dram of pus daily. It had been in this condition for three months. Under these circumstances an attempt was made to effect a cure by increasing the transudation of blood to the infected area. A cupping glass, with rubber exhaust, was employed, of suitable shape and of such a size as to include the sinus and portion of the chest wall bounding the cavity externally. Its application at first was rather painful. It is necessary, however, in such a case, to distinguish between the pain from pressure and the pain from suction, when the area surrounding the sinus is more or less tender. While the cupping glass was in use the patient inflated a football (as he had previously been in the habit of doing for months), in the hope of securing a further local reexpansion, or, it may be, a localized emphysema of the portion of lung abutting on the cavity. The cavity was filled daily with a sodium citrate-chloride solution and the first effect was a notable diminution in the amount of daily discharge. In two months the cavity was quite dry. The author quotes Mr. Godlee as saying that "If we suppose a case in which the various walls of this cavity have been drawn in to the utmost possible extent, there is nothing further to trust to, if things be left alone, than the filling in of the cavity with granulations. Now, when this has gone on to a certain extent, a degree of tension is established which effectually prevents a continuation of the process. A state is then reached in which the pleura becomes lined with a perfectly smooth surface—secreting pus, indeed, but showing no signs of developing fresh granulations." Dick adds that one might suppose (1) that the negative pressure secured by the use of the cupping glass would contribute something in this direction, (*a*) by favoring local pulmonary reexpansion, (*b*) by the induced hyperemia stimulating granulation; (2) that the hypertransudation, which ensued upon the installation of the sodium citrate-chloride solution, would, in conformity with recent pathology, be credited with an inhibition of bacterial activity and a diminution of the tryptic potency of the pus—thus rendering fresh granulations less liable to erosion.

Deutsche medizinische Wochenschrift, August 20, 1908.

Infection with Vaccine.—Eichhoff reports the case of a child in whom vaccination was delayed because of a general eczema from which he was suffering. However, on being bathed in the same tub with his brother who was recently vaccinated, the child received a general infection with the vaccine most of the eczema lesions changing into vaccination pustules. The regional glands were markedly swollen and the temperature elevated. In fourteen days the disease was ended, but numerous scars all over the body were left.

Blood Modifications in Infantile Scurvy.—Prosper Merklen and Leon Tixier made daily examinations of the blood formula in a case of infantile scurvy, before and after antiscorbutic diet, and the use of iron. The blood formula showed constantly a diminution of hemoglobin, but the hypoglobulia, which is usually found, was not constant, and varied with the administration of the iron. After it had been taken for ten days, the formula was normal with regard to red blood cells, showing the value of the use of iron. There was a myeloid reaction shown by the presence of myelocytes, which occur with infections of some duration. The patient suffered from painful pseudoparalysis, and extreme anemia, but showed no hemorrhages.—*Gazette des Hôpitaux*

Book Reviews.

Lehrbuch der Ohrenheilkunde. Von. Dr. Georg Boenninghaus. Berlin: S. Karger, 1908.

This new textbook is intended for students and practitioners. It covers the subject fairly thoroughly in 375 octavo pages. Especial mention should be made of the 140 drawings admirably chosen and showing originality on the part of the author, and of the plate of drum membranes unusually well colored. Except for special details the anatomy is omitted. The description of otoscopic findings is especially good and indicates individual research on the part of the author. Some of the subject matter is both original and, as a whole, up to date. The chapter on functional tests is good both for hearing and equilibration and contains matter far superior to anything that is to be found in English textbooks. The chapter on diseases of the external ear covers the ground well; that, too, on diseases of the inner ear is very satisfactory. The technique and treatment of middle-ear diseases is especially well done, but the description of mastoiditis is too cursory to be valuable. There follow a chapter on central deafness, one on deafmutism, and a short chapter on forensic otology. The book closes with a chapter 16 pages in length in which the subject of operative technique is very insufficiently treated.

School Reports and School Efficiency. By David S. Snedden, Ph.D., and William Allen, Ph.D. for the New York Committee on Physical Welfare of School Children. New York: The Macmillan Company, 1908.

This book is the result of an effort made by the committee named in the title to secure an establishment of an improved system of school reports, that would clearly disclose the various data of interest concerning the New York Public Schools. This effort followed the recognition of the fact that in the present chaotic system of reporting school doings, the publicists, the parents, and all other interested citizens cannot obtain clear ideas as to condition of the schools nor defend by statistical data any changes necessary for the improvement of the public schools.

The book opens with an historical study of the development of school reports during the last century. The succeeding chapters present examples of tables and other forms used in some of the best reports of Detroit, Buffalo, New York, etc. Then follow lists of legitimate questions, some of which are answered in most reports, others are occasionally answered, and others are never answered. Many economies and improvements are then suggested, first in a general way and then in a practical study of a New York City School Report for the year ending July 31, 1906. The mistakes and blunders detected are numerous enough to impress the reader that speedy remedial action is necessary both to save waste in the moneys provided by the taxpayers for the maintenance of the schools, and to furnish support to those who, having the best interests of the schools at heart, strive for progress in the great public school system of our city. The subject of the volume is not limited in its interest to any one profession; it concerns deeply all good citizens and a study of it is as important to the physician as to any other member of the community.

Treatment of Internal Diseases; For Physicians and Students. By Dr. Norbert Ortner, of the University of Vienna. Edited by Nathaniel Bowditch Potter, M.D., Visiting Physician to the New York City Hospital, to the French Hospital, and to the Hospital for Ruptured and Crippled; Instructor in Medicine, Columbia University. Translated by Frederic H. Bartlett, M.D., from the fourth German edition. Philadelphia and London: J. B. Lippincott Company, 1908.

From the editor's preface we quote the following, which will give our readers an adequate idea of the volume: "The scope of the book is indicated in its title: prophylaxis is discussed in but few sections. The author initiates the reader into as much of the pathological physiology of the diseases discussed as bears upon their rational treatment. He very properly emphasizes throughout the volume the importance of the mechanical, dietetic, climatic, hydrotherapeutic, and other extramedicinal methods, with judicious reasons for those selected, and follows with a discussion of the applicability of certain drugs, their respective advantages, disadvantages, and limitations, adds useful prescriptions from his own experience, and that of others, and leaves the reader better armed to meet the etiological indications and the various contingencies which arise and require symptomatic treatment." The editor has done very much more than merely to append his name to the title-page of the work. On nearly every page he has added notes suggesting differences of opinion, criticisms, and additions from authoritative American and English writers; and much of the value of the book is due to his careful and judicious work. The volume is a veritable encyclopedia of treatment, written by a therapeutic enthusiasist who errs, perhaps, by suggesting or naming too many drugs and preparations. Many of the remedies mentioned will shock those who consider it heresy to save a patient's life by means of any drug not stamped with the *sumatur* of the Chicago Council of Pharmacy and Chemistry; but the book will be of much value to every physician whose first aim is to cure or relieve his patients, and who in the discharge of such duty cares not for such "authorities," self-constituted or otherwise.

Golden Rules of Dietetics. The General Principles and Empiric Knowledge of Human Nutrition; Analytic Tables of Foodstuffs; Diet Lists and Rules for Infant Feeding and for Feeding in Various Diseases. By A. L. Benedict, A.M., M.D., Buffalo, Member of American Academy of Medicine, and of American Gastroenterological Association, etc. Author of Practical Dietetics. St. Louis: C. V. Mosby Medical Book & Publishing Company, 1908.

The first portion of this book is given up to the consideration of the daily requirements of the human body in foodstuffs, the standard diet in health, and the composition and preparation of various foods used by man. General hygiene of nutrition is then followed with a number of diet lists taken from many different sources. The rest of the book is devoted to the consideration of the various diseases from the standpoint of the diet best suited to the pathological condition of the gastrointestinal system and the organism in general during the continuation of the disease and in convalescence. An appendix gives directions for preparing the most important and most frequently used dishes, and furnishes a table of foods with the number of calories in a standard portion of each. The book is not intended to take the place of larger treatises on the science of nutrition, but to serve as a ready guide to the physician and the nurse in providing for the adequate and rational feeding of the patient. It forms a very practical manual containing in succinct form the accepted principles of the science and art of dietetics.

The Sexual Question. A Scientific Psychological, Hygienic and Sociological Study for the Cultured Classes. By August Forel, M.D., Ph.D., LL.D. New York: Rebman Company, 1908.

The author of this work is a pronounced idealist and dreamer, and we find him expressing ideas and opinions out of all agreement with present teaching. He advises how to avoid conception in case pregnancy is undesirable; he does not think it altogether wrong for a husband to have intercourse with a woman not his wife, and he believes that love is an irradiation of sexual appetite. But in spite of these revolutionary statements, the volume is entertaining and instructive, and shows a wonderful knowledge of human nature. The entire subject has been studied from every side and not a point is left untouched.

Surgery. By John Allan Wyeth, M.D., LL.D. (University of Alabama); President of the New York Academy of Medicine; President of the Medical Faculty of, and Surgeon-in-Chief to, the New York Policlinic Medical School and Hospital; ex-President of the American Medical Association, of the New York State Medical Association, and of the New York Pathological Society; formerly Attending Surgeon to Mount Sinai and to St. Elizabeth's Hospitals; Honorary Member of the Texas State Medical Association and of the Medical Society of New Jersey; Author of "Essays in Surgical Anatomy and Surgery;" awarded the first and second prizes of the American Medical Association in 1878, and the "Bellevue Alumni Association Prize" in 1876, etc. With 864 illustrations. New York: Marion Sims Wyeth & Company, 1908.

Dr. Wyeth's well-known "Text-Book of Surgery," which first appeared in 1887, and has seen several new editions since, appears now with the new title transcribed above and is issued by a new firm of publishers. This edition is practically a new book, most of the text having been rewritten, and many new illustrations added. The latter are especially good in such chapters as require descriptions of the surgical anatomy of an operative field. The text is concise, well arranged, and very readable. It covers the whole ground of modern surgery, more attention being given to the practical side of the subject, that is, to the symptoms and treatment of surgical affections, than to the pathology of them. There are chapters on such special surgical fields as the eye, the ear, and the male and female genitourinary organs. The index is quite complete and allows the use of the volume for quick reference, but we miss a table of contents giving a general view of the subjects treated. On the whole, Dr. Wyeth's book compares very favorably with other one-volume text-books on surgery and may be recommended to students or physicians looking for such a work.

Society Reports.

THE AMERICAN GYNECOLOGICAL SOCIETY.

Thirty-third Annual Meeting, Held at Philadelphia, Pa., May 26, 27, 28, 1908.

THE PRESIDENT, DR. J. MONTGOMERY BALDY OF PHILADELPHIA IN THE CHAIR.

(*Concluded from page* 468.)

President's Address.—President BALDY in his address discussed the general policies, advances, and failures of the past, as well as the duties of the future. The objects of the society were of a mixed character, scientific and social. The social side brought men together, gave opportunity for personal contact and the estimate of personal worth, and no better way existed of discovering an individual's professional capacity than to become acquainted with his methods of thought, accuracy of observation, and process of reasoning as applied to those everyday affairs with which everyone, scientist or layman, was equally well acquainted and of which he was equally competent to judge. In looking over the field of endeavor for the past year he found nothing new advanced, nor any startling improvement on the old. After a decade of obstetrical and gynecological activity, unprecedented in any branch of medicine, he said that gynecologists were like wise men who seemed to be resting, retrospecting, and putting their houses in perfect order before proceeding further. Notwithstanding this, the signs for the future were bright, and when it was noted on the one hand the activity of the obstetrical world in that great undertaking, the prevention of blindness at the beginning of life, and the activity of the gynecological world in the fight against cancer, we might look with complacency upon the criticism which had predicted the end of gynecology as a specialty. President Baldy then discussed the general administration of anesthetics as performed to-day, and expressed the hope that an anesthetizer would be placed in each and every hospital in the land with a salary of sufficient size to attract to the service men or women of proper intelligence. Many brainy women fully capable of being trained to give anesthetics had entered the nursing profession and it was from this source we must look for a solution of the difficulty. Women were being tried and were proving most satisfactory as anesthetists, and it would be a bright day of advance in the technique of the operating room when their services were more generally adopted.

The Development of the Technique of Gynecological Operations.—Dr. AUGUST MARTIN of Berlin, Germany, presented a review of the work done by gynecologists in the past fifty years, and said the basis of the increasing value of gynecological operations was the advance in anatomy, normal and pathological, and in diagnosis. Asepsis insured surgical results. He said there were two routes in the front of discussions regarding operation to-day, the abdominal and the vaginal, and he described the indications and limitations of each.

Abdominal and Vaginal Gynecological Operations; Their Indications and Techniques.—Dr. F. PFANNENSTIEL of Kiel, Germany, followed with a paper on this subject in which he pointed out that either method was available for the majority of gynecological operations. The route which gave primarily and secondarily the best chances for life and health for the patient was to be preferred. In all intraperitoneal procedures the best chances were given by abdominal celiotomy, as it afforded a better opportunity for either radical or conservative work. In aseptic cases, tumors, extrauterine pregnancy, chronic inflammations, malformations, etc., the abdominal route was preferable. In septic cases, when the indications were that the infectious matter could be completely removed, the vaginal route was preferred, unless a complete view of the whole field of operation and its surroundings was necessary. Except in early invasion of the cervix, all cases of cancer were better treated by the abdominal route; also when involvement of the appendix was suspected. Vaginal operation accomplished most in all cases of prolapsus or descensus (genitoptosis) and movable retrouterine displacements. Here neither suspension nor the Alexander operation with or without colporrhaphy was permanent. Anterior and posterior vaginal celiotomy were used, sometimes the one, sometimes the other, and, if necessary, both. The author then pointed out the advantages of the Pfannenstiel transverse abdominal incision.

Vertical and Horizontal Amputation of the Uterus.—Dr. HOWARD A. KELLY of Baltimore said that supravaginal hysterectomy in women under forty was too radical if it could be avoided. He spoke of subsection of the body of the uterus as being a better plan, retaining the uterine mucosa, cutting the flow down to normal, and preserving the function of menstruation. He then described the methods of vertical and horizontal subsection of the uterus.

Cesarean Section Necessitated by a Previous Ventrofixation.—Dr. EDWIN B. CRAGIN of New York said that the fact that dystocia following ventrofixation should occur six times in the experience of one man, and be so marked as to indicate cesarean section, was sufficient evidence of the frequency of this sequel to the operation. As these fixation operations were all performed by different operators, the personal equation was eliminated. In spite of attention being called to the possibility of this unfortunate sequel to ventrofixation, ventrosuspension was still quite frequently performed. An intended ventrosuspension might become a ventrofixation by accidental wound infection. A ventrosuspension, which allowed an easy labor, if a febrile puerperium occurred in the first postoperative confinement, might become a ventrofixation and demand a cesarean section for the next delivery, as occurred in the last of this series. During the child-bearing age, ventrofixation was not a safe operation for posterior displacement of the uterus.

Is Pubiotomy a Justifiable Operation?—Dr. J. WHITRIDGE WILLIAMS of Baltimore in a paper on this subject stated that in thirteen operations performed by him or his assistants there were no maternal deaths, only one woman being seriously sick. All of them began to walk by the end of the third week and were dismissed in good condition less than one week later. In one-third of the cases there was permanent mobility between the cut ends of the bone. This did not interfere with locomotion, and possibly played a part in permitting subsequent spontaneous delivery in one patient. The operation was contraindicated when the conjugata vera measured 7 cm. or less, and consequently did not enter into competition with cesarean section, except at the uppermost limit of the classical indication. It was particularly applicable to the "border-line" cases, as it afforded a safe method of delivery after subjecting the patient to the test of several hours in the second stage; whereas the mortality of cesarean section rose steadily with each hour elapsing after the onset of labor. If pubiotomy fulfilled its present promise, it should entirely do away with the induction of premature labor in the treatment of contracted pelves.

An Experimental Study on Hemorrhage Following the Cutting of the Uterine and Ovarian Arteries in Dogs and Its Possible Bearing on Ruptured Ectopic Pregnancy.—Dr. HUNTER ROBB of Cleveland said that attempts were made to cause lesions in dogs which would correspond in severity to those present in cases of ruptured ectopic pregnancies in women. The experiments, which numbered in all twenty-nine, might be divided into the following series: (1) Division of the uterine and ovarian vessels. Not one of the fourteen dogs died as the result of the hemorrhage. Probably the woman rarely if ever died of the hemorrhage *per se*. (2) Division of the uterine artery producing shock. Secondary operation on the dog

while in a condition of shock. This single observation in which the dog died was at least suggestive in showing that there was danger in giving an anesthetic or in carrying out an operation while shock was still present. (3) Division of the uterine vessels and observation on the blood-pressure and hemoglobin. As would be expected, there was a fall in blood-pressure and hemoglobin percentage immediately after incision of the vessels; as soon as the hemoglobin percentage stopped going down the blood-pressure began to rise again. (4) Division of the uterine vessels and observations on the pulse, respiration, and hemoglobin, with especial reference to the timing of the clotting of the blood. Immediately after the cutting of the vessels the pulse and respirations had improved and the hemoglobin remained stationary. On opening the abdomen it was found that the bleeding had ceased and clotting had taken place. (5) Division of the vessels, observation on the pulse, respiration and hemoglobin before and after bandaging and after applying weights to the lower abdomen. The application of bandages and, better still, the application of weights to the abdomen improved the pulse and respiration and caused the hemoglobin to remain stationary, *i.e.* these procedures favored a cessation of the hemorrhage. (6) Division of the uterine vessels with the dog in the upright position; observations on the pulse, respiration, and hemoglobin. With the dog in the upright position the pulse and hemoglobin were kept in better condition than when the dog was allowed to remain in the horizontal position.

Assuming, then, that in these experiments conditions were produced similar to those occurring in ruptured ectopic pregnancies in women, the results suggested the following conclusions as being worthy of consideration: (1) A woman suffering from a ruptured ectopic pregnancy does not die from the hemorrhage itself. Death is caused by hemorrhage and shock, which might be increased by various procedures. (2) An immediate operation might add shock to shock and so prevent recovery. (3) The hemorrhage ceases in from fifteen to twenty minutes. The fact that the hemoglobin remained stationary showed that clotting had taken place. A hemorrhage that had ceased might be started up by manipulation of the tissues, and might thus be mistaken for a continuing hemorrhage. (4) The subcutaneous injection of salt improved the pulse and respiration and did not start the hemorrhage up again. (5) The use of bandages or proper weights by which the abdomen walls were approximated was likely to improve the condition of these patients.

The following papers were also read: "The Condition of the Mucosa in Cases of Uterine Myomata," by Dr. Thomas Cullen, of Baltimore; "Intraabdominal Pressure," by Dr. Richard R. Smith, of Grand Rapids, Mich. "The Surgical Treatment of Prolapse of the Uterus and Bladder," by Dr. I. S. Stone, of Washington, D.C.; "Endometritis Exfoliativa," by Dr. Hugo Ehrenfest, of St. Louis, Mo.

Officers Elected.—The following officers were elected for the ensuing year: *President,* Dr. J. Riddle Goffe of New York; *First Vice-President,* Dr. Howard A. Kelly of Baltimore; *Second Vice-President,* Dr. Malcolm McLean of New York; *Treasurer,* Dr. J. Wesley Bovée of Washington, D.C.; *Secretary,* Dr. Leroy Broun of New York; *Members of the Council,* Drs. George Tucker Harrison and J. Montgomery Baldy of Philadelphia. New York was selected as the place for holding the next annual meeting.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Thirtieth Annual Meeting, Held ot Montreal, May 11, 12, and 13, 1908.

(Special Report to the MEDICAL RECORD.)

DR. HERBERT S. BIRKETT OF MONTREAL, PRESIDENT.

(*Concluded from page 405.*)

Tuesday, May 12—Second Day.

Methods of Opening the Maxillary Antrum.—Dr. JOHN O. ROE of Rochester read a paper with this title and enumerated the various operations which have come into vogue during the last few years. He emphasized the advantages of the nasal route over all others. The success of this latter method no matter what special modification of it was followed depended on the freedom of the opening which allowed perfect drainage and gave free access to every portion of the cavity. The lower portion of the turbinate was removed first with either knife or scissors. An incision was then made through the periosteum down to the bone from behind forward, covering the entire length of the antrum. The first puncture should be made over the forward projection of the antrum and at this point the incision through the periosteum was turned downward as far the the floor of the nose. This flap was then raised from the bone, carrying periosteum with it, throughout this subturbinal portion of the wall and rolled into the center of the nose out of the way. An opening was then made into the anterior portion of the septum as close to the floor as possible. This was enlarged with any instrument preferred, the cavity was carefully explored, curetted, and dried out. The periosteum which had been raised from the inner wall was trimmed and then turned down over the stump of the wall and held there by iodoform gauze packing. Thus a uniform mucous surface was left and a perfectly free opening into the cavity. The patient could easily irrigate through such an opening himself and absolutely free drainage was maintained. Danger of recurrence was avoided, even in face of infection, and there was no necessity for an external operation. A new model of antral perforator was exhibited.

Dr. HARMON SMITH described the instrument which he was accustomed to use in perforating the antrum. He did not believe it very practicable to attempt to save the antral mucosa because we often pulled it away entirely in making the first change in the dressing. Dry packing was best.

Dr. W. E. CASSELBERRY believed that the best instrument was one which would cut forward after it had entered the antrum.

Dr. J. PRICE-BROWN of Toronto believed that such an instrument as Dr. Roe had presented was useful in chronic cases but there was some danger of atrophy resulting if a permanent connection between antrum and nasal fossa was made in young patients. In the latter class, the operation by the canine fossa route was preferable.

Dr. EMIL MAYER was in general strongly in favor of the intranasal route and wished to protest vigorously against the unclean habit of having the patient's mouth bathed with antral pus as was the case when the buccal route was taken. It was possible to cure chronic cases by intranasal drainage and he had had much satisfaction in using the chisel devised by Dr. Myles which had a large end and pulled forward, thus meeting the desideratum mentioned by Dr. Casselberry.

Dr. J. H. BRYAN named as an objectionable feature of the intranasal operation the fact that if the opening was made in the inferior meatus or in the region of the anterior extremity of the inferior turbinal, the opening thus left might prove of great embarrassment to the patient. This operation would not cure all cases, for we could not curette the entire antrum through the inferior meatus.

Only through an anterior opening could we remove all the diseased mucosa.

Dr. T. P. Berens of New York said we must determine whether the antrum was merely a pus reservoir or the actual seat of disease. The discharge might come from above and our procedure would depend on the finding as to this matter, in each individual case. Dr. Roe had not made it clear to the speaker just how he decided this point in diagnosis and selected his cases for the intranasal operation.

Dr. J. W. Gleitsmann was in accord with Dr. Bryan and said that what we needed was a more thorough knowledge of the etiology and diagnosis of these conditions and as simple methods of treatment as possible.

Dr. L. A. Coffin said that his custom was to do a radical frontal or ethmoidal operation on one side and treat the antrum secondarily, and do, as had been suggested by Dr. Bryan, the radical operation through the canine fossa opposite the middle turbinate.

Dr. E. Fletcher Ingals spoke of the excessive zeal of some men in the line of operating on sinus cases. One did not need a sledge hammer to drive a tack. He believed that 80 per cent. of antral cases and more than that number of frontal cases could be cured by a comparatively mild operation through the nose. It was better to act mildly at first for we still had the radical procedure in reserve.

Dr. J. H. Bryan believed it impossible to cure a chronic antral suppuration without a radical operation.

Dr. W. L. Ballenger of Chicago believed that a large percentage of inflammations, even chronic, of the cells draining anteriorly into the infundibulum could be cured without a radical operation. The ends to be attained were free drainage and ventilation, and even in the presence of granulation and bare bone, cure would result if we could establish the two conditions named. He had found radical operations necessary in only about three per cent. of a group of 200 cases.

Dr. Berens would admit that 80 per cent of all the cases we saw would recover without radical treatment but the objection to intranasal surgery in these cases was that we could not always see what we were doing. The dropping of pus into the mouth was not a necessary consequence of the canine fossa operation, for the canine opening could be stitched so as to prevent this.

Dr. Roe said, in closing, that he was accustomed to make a small opening through the nasal wall and then explore with a probe in order to determine whether the antral wall was lined with mucous membrane or whether the cavity was full of granulations and the mucosa spongy. Through this opening he inserted a small cannula and made further explorations. One could medicate every portion of the antrum by means of remedies applied on a cotton-tipped bent probe. He did not believe in scraping out the antrum and leaving its surface a great scar. We should give the membrane time to recover.

Abscess of the Larynx Following Pneumonia.—Dr. T. Melville Hardie of Chicago reported the case of an Italian laborer of 43 years admitted to hospital with pneumonia. Resolution came in nine days but he still coughed frequently and had some pain in the throat. Next day there was considerable dyspnea and laryngeal edema could be made out. Two days later tracheotomy under local anesthesia was called for. After exposure of the cricoid and upper trachea an irregular enlargement was made out on the left side of the larynx and incision of it evacuated some pus. Diplococci (probably pneumococci) were found in pure culture. After a serious illness the man recovered.

Dr. H. L. Wagner said it was interesting to note the different effects the pneumococcus had on mucous membranes and adjacent structures. In one instance in a case of pneumonia an acute swelling was found on the inside of the nose and both sides of the septum and then going externally giving the picture of erysipelas. From this inflamed area a pure culture was obtained similar to that from the nose and septum.

Further Report of a Case of Tracheal Scleroma.—Dr. Emil Mayer of New York City gave the further history of the case reported by him in 1906. Ten months later the patient presented herself with hoarseness and dyspnea and it could be seen that the growth had recurred. She was submitted to *x*-ray treatment through an extensive tracheotomy wound made for the purpose, the incision being three and one-half inches long, from the lower edge of the thyroid cartilage to about three-quarters of an inch above the sternal notch. The isthmus of the thyroid was divided between ligatures. Exposure was made under chloroform at first but without it later. Six weeks of this form of treatment had a most happy result and she left the hospital apparently cured. Seen one year later she reported that she had continued well, without dyspnea, hoarseness, or cough. Examination of the larynx and trachea showed perfectly normal conditions, with no trace of recurrence. In case of later recurrence the author thought that application of the *x*-ray over the cicatrix of the tracheotomy wound would promise good results, as this would not present the same resistance as the normal tissue would; or this failing, it would be easy to reopen the former wound and renew the direct exposure.

Subglottic Papilloma; Branchiogenetic Cyst.—Dr. Thomas J. Harris of New York City reported these cases. Case 1 was that of a boy of 11 years with subglottic papilloma which was attached under the surface of the right cord. Attempts at endolaryngeal removal were unsuccessful owing to the extreme irritability of the throat, an overhanging epiglottis, and a very poor general condition. He was admitted to hospital and another attempt made with the tube-spatula. In this way a part of the growth only could be taken off and laryngo-fissure was decided on with a preliminary tracheotomy. There was considerable reaction but this finally subsided and it was proposed to insert an intubation tube on account of persistent swelling of the cords though all traces of the papilloma had disappeared. The child was intubated, but in a few hours he began to have severe dyspnea and the tracheotomy tube was introduced. The intubation tube could not be seen in the larynx and events proved that it had been dislodged and swallowed as it came through in the stools. After a while another intubation tube was introduced and remained in place for a few days and then disappeared nor was any trace of it found afterward. The boy did well, however, and eventually made a good recovery.

Case 2 was that of a branchiogenetic cyst occurring in a Russian woman of 30 years who complained of a feeling of discomfort and occlusion in the region of the nasopharynx. Digital examination revealed a growth suggesting a cyst and filled with pulpy material like adenoids. The mass was easily removed with the forceps. Sections showed the tissue to be made up mainly of lymphadenoid structure. One surface showed the normal stratified epithelium of the pharynx. There were a few mucous glands and scattered through the section in several places were tubules lined with ciliated columnar epithelium. Beneath this epithelium the tissue had the appearance of embryonal connective tissue and the growth was evidently the remains of a branchiogenetic cleft.

Some Surgical Emergencies Associated with the Tuberculous Larynx.—Dr. Charles P. Grayson of Philadelphia made in this paper a plea for a more hearty and earlier association of the family physician with the specialist in caring for the laryngeal lesions arising in the ordinary course of pulmonary tuberculosis. There should be no such thing as emergency surgery in laryngeal tubercle. Much could be done to prevent certain complicating lesions but it must be done by one accustomed to intralaryngeal manipulations. Several personal cases were detailed illustrating the points made by the writer. In

one case a hurried tracheotomy was done to prevent asphyxiation. In a second an abscess was threatening life and called for evacuation. In a third a tracheotomy was called for on account of sudden edema. Such experiences were happening frequently not only in the country districts but in large cities where the aid of the laryngologist could be easily secured.

Dr. W. E. Casselberry said that it was not always possible to prevent such complications as had been mentioned by Dr. Grayson. They would come on in spite of every precaution the specialist might take.

Dr. Price-Brown would emphasize the value of rest in laryngeal tuberculosis. In one instance he had been obliged to do a tracheotomy but the rest afforded the larynx by the operation had sufficed to keep the patient alive for over five years. One-half of the epiglottis was gone and the upper orifice of the larynx was greatly contracted. Yet the man was able to work eight hours a day and the local process had been brought to a standstill.

Dr. J. O. Roe would regard tracheotomy only as an emergency measure, but functional rest could be obtained by abstinence from conversation. Nothing less than absolute silence was efficient.

Dr. J. W. Gleitsmann called attention to the dangers arising in the use of tuberculin. He had been very careful in selecting the dose, had always had his patient under close observation, and had never seen any bad effects. He always examined the chest and eyes after each injection. He believed there was some chance of relieving these cases if the patient could live and work in a hygienic environment with an abundance of good food.

Papilloma of the Larynx in Children.—Dr. J. Payson Clark of Boston reported the later history of four cases which he had presented to the Association in a paper read three years ago. He also reported four new cases and reviewed the literature of the last three years. The entire number of cases reported was 18. In ten tracheotomy had been done with five fatalities. The author was of the belief, however, that in the prolonged and obstinate cases a preliminary tracheotomy offered a better chance of permanent recovery and avoidance of recurrence than does a laryngofissure. Desirerata of treatment were (1) that we should get rid of the growth as soon as possible and with the least risk to the patient; (2) that the voice should be not impaired, and (3) that (in girls at least) there should be no external scar. The author dismissed laryngofissure as never applicable. A new case should be watched for a few weeks and if no increase in size took place one might try removal without tracheotomy using straight instruments and direct vision. Such neoplasms would not yield to any form of treatment until their period of active growth had been passed, or until they had lost their power of reproduction. There were no data on which to estimate the duration of this period, hence the wisdom of the above named course of action. In all our manipulations the utmost care must be taken not to wound the mucosa as this trauma may be the site of a new papilloma. The advisability of operating without a previous tracheotomy in cases with dyspnea must be decided in each individual instance. Apart from the curative value of tracheotomy there could be no question that it made the subsequent removal of the growth easier and safer. The risk of bronchopneumonia following (immediately or eventually) tracheotomy was a real one, but in case of a large and rapidly-growing papilloma or one recurring rapidly after removal without tracheotomy, the only alternative was suffocation.

Dr. A. Coolidge, Jr., coincided in every respect with the views of Dr. Clark. As regarded treatment, cases of papilloma could be divided roughly into two classes: (1) Those which occurred in young children and (2) those occurring in children old enough to allow one to put in any instrument for inspection and treatment. This age might be between seven and ten years. Before that age a tube having once been inserted, it should stay in till all traces of the papilloma had disappeared. Frequent operating and laryngo-fissure are to be condemned. Children might die from many causes if the tube was removed too early.

Dr. D. Bryson Delavan referred to the tube devised by Dr. John Rogers of New York. He was in general accord with the views expressed in the paper and called special attention to the dangers of ill-fitting tubes.

Dr. Harmon Smith believed that there must be some pathological difference between a single-papilloma even when large, and the multiple variety. The former were not so apt to recur. The more the latter were removed, the more they seemed to recur. If, however, we could put the larynx at rest, the growths might cease to reproduce themselves.

Dr. Emil Mayer asked if anyone present had had experience with the local application of alcohol in these cases.

Dr. H. L. Swain had seen some success follow the use of alcohol as suggested. He had had no experience with either iodine or carbolic acid which had been suggested by some writers.

Dr. E. Fletcher Ingals would feel like urging a tracheotomy in all cases in which there was dyspnea, before attempting an operation for removal. He had seen no benefit from the use of alcohol, but had seen one papilloma cease to recur following the use of iodine and carbolic acid.

Dr. F. E. Hopkins had seen pressure from an intubation tube cause the papilloma to disappear, but irritation of the region resulted with ulceration of the vocal cord. A hard rubber tube instead of a metal one might have afforded better results.

Dr. Clark said, in closing, that in none of his cases was the dyspnea so severe as to prevent him from doing a tracheotomy. He had never been called on to insert an intubation tube to prevent suffocation. Tracheotomies done at leisure left less conspicuous scars than those done hurriedly.

Essentials in Voice Production.—Prof. Wesley Mills of the McGill University Medical Faculty and a Guest of the Association, delivered a short address on this subject. The laryngologist must show in order to influence his patients a sympathy with them and some knowledge of musical sound as far as it went. There were so many methods of vocal teaching now before the public that one was at a loss to know what plan to adopt. Prof. Mills laid down as essentials the following points: Speaking and singing are in reality the same. The physiological adjustment of the various parts of the vocal organs is the keynote of the whole question. Practically all respiration exists for the expiratory blast. The principal adjustment is between the expiratory action of the respiratory mechanism and the vocal bands, known as the "attack." This is completed by a further adjustment of the upper or resonance chambers to the parts below. One speaks with the tongue and should on no account speak with the throat. He must speak from the throat into the resonance or upper chambers, that is, he must speak towards his face. He must especially speak and sing with that part of his mouth cavity lying between the soft palate and the teeth. He must keep the back of the throat and the front boundaries of the mouth cavity out of the way. He must never strain or use more force in phonating than the organ can bear without suffering. Artistic speaking and singing are always physiological. Vowels alone are musical and consonants are necessary nuisances but deserving of close attention. The speaker performed some simple experiments illustrating resonance. He deplored the prevailing slipshod methods of pronunciation in daily life, on the stage and in the concert hall. The present generation was given to a nasal tone owing to the laziness that allowed the tongue to roll up and back and the soft palate to drop and meet it so that the breath stream must pass through the nose. Prof. Mills would lay great stress on exclusive

mouth breathing in phonating. In mouth breathing the tongue flattened, the soft palate tended to rise, and the totality of the mouth parts were put into the best form for the utterance of pure vocal sounds. Under such circumstances nasality became relatively difficult, and in absence of mouth breathing it was very difficult, to cure. All faulty methods of voice production tended to produce venous congestion with a corresponding starvation and poisoning of the tissues of the vocal organs owing to the fact that the blood was kept too long in the capillaries.

Essentials of Speech Production.—Dr. G. Hudson Makuen of Philadelphia spoke of the method of voice formation and of the differences of the voices for speech and song respectively. He then took up the matter of articulation and considered the central mechanism of speech as distinguished from the peripheral mechanism. The chief receptive avenue for speech was of course through the hearing: but vision also played an important part. The chief motor center was Broca's center, as it was called, at the posterior portion of the third frontal convolution, and in it were stored the memories for the varied movements used in the production of speech. Modern theories suggested that the Broca center was really sensory rather than motor as it shared with the visual and auditory centers the function of serving as a storehouse for sensory impressions. On this theory the motor center for spoken words lay in the medulla. The order of cerebral activities in the production of speech therefore was first the revival of word images in the auditory center (and in some cases in the visual center) by means of afferent impulses from without through the special senses, or by means of impulses from the higher intellectual centers from within the brain: second, a transmission of these impulses from revived images in the auditory and visual centers through commissural fibers to the Broca center; and third, a revival of the kinesthetic word images which in turn incited to action the motor centers in the bulb. For such physiological results we must have the following conditions: (1) the mechanisms must be structurally normal and free from pathological encumbrances, such as dental, alveolar, and palatal irregularities, enlarged tonsils, nasal obstructions, and cerebral tumors; (2) the various parts of the individual mechanisms must be accurately coordinated; (3) there must be a similar coordination of the mechanisms themselves; (4) this accuracy of vocal and articulatory musculature must be largely automatic, and this in turn was brought about mainly through psychophysical development and training. The speaker said that he always advised the removal of enlarged tonsils in singers and had never seen any bad effects follow. Children inherited bad speech tendencies, and a bad environment in this respect encouraged bad speech. He believed that the diaphragm should be confined entirely to expiration and never used for inspiration. What he meant by diaphragmatic breathing was not to use the diaphragm at all for inspiration but to use it artistically in the production of voice.

Dr. J. W. Farlow remarked that one difficulty in instructing patients in the use of the voice was that they did not hear the sound of their own voices as it appeared to other people. This was easily realized by any one who spoke into the recording apparatus of a phonograph and then listened to his own voice as recorded on the cylinder. He would lay stress on the importance of careful attention to the use of the voice by children. Comic operas and stage darkies with all their slang and loud talking were most demoralizing to the ordinary listener and were responsible for much of the modern abominable vocal methods of every-day life.

Prof. Mills said that occasional joint conventions between teachers of singing and laryngologists would be of great service. The voice teachers differed much in their use of terms and much confusion was caused thereby. The influence of great teachers was after all but a tradition. He was not prepared to admit fully that the Broca center was a sensory affair. The recent experiments of Sherrington and Gruenbaum seemed to prove that all this region was motor. There was a tendency also to recast the entire subject of aphasia for it was not believed that the present system of localization was at all satisfactory. His ideal of a voice teacher was one who would in a large measure combine in himself the physiologist, physician, laryngologist, and musician. He had found that the throats of singers were, as a rule, comparatively dry, and believed that too much moisture was a distinct disadvantage, especially when occurring on the vocal bands. Childhood was not too early to begin correct instruction in speaking. He did not believe that the removal of the tonsils affected the pitch of the voice, and in the case of a patient who might claim that it did, he would say that the patient had not learned how to sing correctly. Contrary to the view expressed by Dr. Makuen, he must insist that the diaphragm was an inspiratory and not an expiratory muscle.

Wednesday, May 13—Third Day.

The Morphology of the Turbinals.—Dr. John M. Ingersoll of Cleveland, O., gave a description of the turbinal bones as occurring in fishes, loons, reptiles, panthers, apes, and man, illustrating his remarks with some excellent drawings. His recapitulation was as follows: The turbinal structures of fishes except dipnoi were used only for olfaction and were simply ridges covered by olfactory mucous membrane. In reptiles, owing to the changed manner of respiration, the nasal organ functionated both in respiration and olfaction and both respiratory and olfactory turbinals were found. They were, however, quite simple structures. In birds the importance of the respiratory function increased and the respiratory turbinals showed a high degree of development. The expanse of respiratory mucous membrane was very largely increased by the coiled structures of the turbinals. The olfactory turbinals were simply ridge-like structures. In microsmatic mammals all of the turbinals exhibited a very high degree of development. Their numerous fine branches and coils enormously increased the amount of mucous membrane exposed within a comparatively small space and thus increased the efficiency of the nasal organs. In apes, all of the turbinals had degenerated or reverted to some of the more primitive types. In man the turbinals were quite similar to the turbinals of the ape and were all rather simple structures. Rudiments of the fourth and fifth ethmoidal turbinals were sometimes found. The agger nasi was the rudiment of the nasal turbinal. Such rudiments were much more frequently present in the embryo than in the adult.

Dr. D. Bryson Delavan called attention to the fact that in saw operations on the septum we often came in deep section on a slightly oval space, which might be the remains of Jacobson's organ or of the channel leading to it. It was difficult to explain its origin and the line of communication through the hard palate with the mouth.

Dr. W. E. Casselberry had never been able to find the space referred to by the previous speaker.

Dr. H. P. Mosher said that in discussing Jacobson's organ we were greatly helped by comparative anatomy. He described the appearance of this organ in the human fetus and its gradual evolution to the condition found in the adult.

Hypertrophic Form of Syphilis Involving the Fauces and Epiglottis.—Dr. W. F. Chappell of New York City reported the case of a boy of 14 years who had previously been treated in hospital for tonsils and adenoids. Some four years later he again came under observation, with symptoms of snoring in sleep, guttural voice, labored breathing, and dyspnea on ex-

ertion. Frequent choking and strangling spells came on, though the boy seemed in perfect health. Examination showed both faucial pillars hypertrophied and much hypertrophic tissue occupied the position of the tonsil. The uvula was much enlarged in each dimension and nearly filled the pharyngeal cavity and was probably the cause of the choking. The same condition existed in the epiglottis, which had lost its flexibility and allowed food to enter the larynx. The arytenoids shared in the general hypertrophy. No implication of other laryngeal structures could be made out. The mucosa covering all these parts was grayish, smooth, and shiny. Adrenalin had no particular effect on the hypertrophied tissue. A portion of the uvula was removed, with much relief to the symptoms of choking and strangling. Examination of the portion of the uvula excised suggested a diagnosis of hereditary specific infection, though nothing corroborative could be obtained in the personal or family history. Under mixed treatment and later Donovan's solution of arsenic and mercury, considerable improvement resulted, but considerable hypertrophy of the parts involved still remained. Most of the obscure cases of pharyngeal hypertrophy on record had proven to be of an amyloid nature. Such a case as the author's was unique.

Membranous Tertiary Syphilitic Lesions.—Dr. D. Braden Kyle of Philadelphia reported three cases reresembling Vincent's angina. In all there was a membranous deposit on various areas in the throat. All the patients were males over thirty years. The membrane could be easily stripped off and left a ragged, worm-eaten surface, which bled easily. There were no associated systemic symptoms at the time. The symptoms were the usual ones of irritation from an ulcerated condition in the mouth. In all there was a denial of specific disease. All sorts of remedies were applied without avail, and then the iodides and finally mixed treatment, but without result. The membrane continued to form and the ulcerations grew deeper. Bacteriological examination was non-decisive in one case; the two other cases revealed Vincent's spirilla, but many other bacteria as well. The author finally decided that in spite of the negative results of treatment the cases were specific and that if the patients would enter the hospital and receive treatment by inunction and obtain the proper nourishment, they would recover. His surmise proved correct, as inside of ten days the membranes began to disappear and recovery was fairly rapid. Up to the present time there had been no relapse, though there was slight scar tissue in the mouth. The author's aim in reporting these cases was to note (1) the unusual form of tertiary lesion, (2) its close resemblance to Vincent's angina, and (3) the importance of the therapeutic test. In the cases with Vincent's spirilla he did not believe a mixed infection was present, but that the presence of the latter organism was purely accidental.

Cysts, Abscesses, and Edema of the Epiglottis.—Dr. Henry L. Swain of New Haven reported several cases and discussed their pathology. In the depths of the branchial clefts in the embryo, epiblast and hypoblast were seen separated by only a network of a single layer of fibers. An inclusion cyst such as these epiglottis cysts were, might come on one or the other side of the partition, but when in later years these cysts filled up, the swelling would be at the base of the inside or outside of the epiglottis. Also in the region under discussion we might have dermoid cysts and supernumerary thyroid glands. The exact cause of the sudden swelling of all these structures was often obscure. They might become infected from some previous inflammation, but often their enlargement, with the usual symptoms of throat discomfort and mechanical disturbance of the parts, was the first thing noticed. The indications for treatment were plain and clear. Dr. Swain also reported three cases of what he called "idiopathic inflammatory edema of the epiglottis," for lack of a more definite name. The attacks were in no way connected with previous disturbance in the throat. In one case there had been a leptothrix deposit on the tonsils, which had caused considerable disturbance. In this case the trouble was supposed to have been due to a small abscess, which could not be located, but which, from the sudden subsidence of symptoms, had evidently ruptured. In the former two instances the simplest explanation would be to assume the existence of a perichondritis, which was accompanied by edema and pus formation. It might be that there was an inflammation of a small retention cyst on the epiglottis.

Dr. W. E. Casselberry said that Dr. Swain had grouped two classes of disease which had received very little attention in literature. We quite frequently met with cysts in the region of the larynx, epiglottis, aryepiglottic folds, and base of the tongue classified simply as "cysts," but it might well be true that branchial cysts occurred in the region of the epiglottis. As to those cases resulting from idiopathic inflammations of the epiglottis, we must remember that most conditions in this region formerly styled idiopathic were in reality infections and caused by microorganisms. This was notable in some epidemics of diphtheria in which some cases seemed to show an exudate, while others showed merely edema, and yet in both we found the Klebs-Loeffler bacillus.

Dr. J. E. Newcomb said that diphtheria always meant the presence of a membrane somewhere, although it might be only a small patch down in a bronchus, but the old conception of diphtheria without membrane must be given up.

Dr. Emil Mayer referred to a case of inflamed epiglottis causing obstruction, for which a tracheotomy was about to be done, but under hot inhalations and adrenalin applications the swelling had subsided. Later, after the case had cleared up, it was noted that more than half of the epiglottis was gone, and his final conclusion was that the case was one of acute inflammation of that portion of the epiglottis remaining after a previous specific destruction.

Dr. E. Fletcher Ingals had recently cured a cyst of the aryepiglottic fold by aspiration and injection with iodine and carbolic acid.

Dr. J. M. Ingersoll had treated two retention cysts of the epiglottis by simply cutting the tops off, and there was no recurrence.

Prolonged Intubation in the Adult.—Dr. W. K. Simpson of New York reported the case of a woman who had come under observation in 1903. For five months she had been wearing a tracheotomy tube inserted on account of urgent laryngeal dyspnea. The latter had come on in connection with a severe cold, during which she had cough, hoarseness, and increasing difficulty in breathing, so that tracheotomy became necessary. She greatly desired to be freed from the wearing of the tube. Examination of the larynx showed it to be practically closed, all the landmarks being obliterated. The superior portion, including the arytenoids, was incorporated in a more or less uniform bilateral mass of a rather dense character, leaving a mere slit in the center. There was no apparent loss of tissue and practically no motion of the parts. Antisyphilitic treatment was given, though the question of old specific infection was doubtful. Results were not at all definite. Finally, under chloroform, a medium-sized hard-rubber intubation tube was passed and the tracheotomy tube withdrawn. The tube was worn well, but was finally coughed out and replaced, and this happened several times. Still later, the tracheotomy slit was closed. In due time the intubation tube was re-

moved, having been worn over four years. At the present time the voice was in fair condition. At times the quality was excellent, but it became hoarse on slight cold. The laryngeal color was rather pale. Motion was somewhat restricted owing to induration about the left cricoarytenoid joint, while the right side moved more freely. The right cord was fairly normal in contour, color, and motion, while the left seemed to have been more or less absorbed. The glottic space, though irregular, was ample for breathing. The author would lay stress on the following points: (1) The tolerance of the larynx to long-continued pressure; (2) the superiority of such pressure in causing absorption over the older methods of temporary introduction of dilating instruments; (3) the comparative comfort with which such tubes might be worn indefinitely; (4) the improved general condition of the patient while wearing an intubation tube in contrast to the debilitating influence and local annoyance of the tracheotomy cannula; (5) the superiority of the hard-rubber over the metal tube in the lessened formation of calcareous deposit, thus lessening the dangers of ulceration and formation of exuberant granulation tissue.

The Question of Rheumatism Originating Through Tonsillar Infection.—Dr. George B. Hope of New York City presented a paper with this title. He traversed the familiar paths of the discussions of the last few years on this mooted question and declared his disbelief in the theory that rheumatism gained access to the body through the tonsils. These organs did not disseminate bacterial infection to the degree commonly conceived. Bacteria were rarely allowed to pass beyond the capsule into the surrounding lymph nodes to develop active inflammatory processes. Hope believed that the theory of a tonsillar infection with reference to rheumatism rested on inference rather than on proven facts. Tonsillectomy for this condition was as illogical as rubbing the joints for the prevention or cure of arthritic rheumatism. Hypertrophied and indurated tonsils should be removed, it is true, but this was a matter wholly independent of their having a causative relation to rheumatism.

The Treatment of Inoperable Tonsillar Hypertrophy by Interstitial Injections of Silver Nitrate.—Dr. J. L. Goodale of Boston presented the results of his observations on injections of enlarged tonsils with silver nitrate. Three cases with hemophilia and tonsillar enlargement had recently come under his observation, and crypt dilatation with cheesy detritus was evidently to blame for the infectious arthritis present in all the cases. One objection to the employment under such conditions of chromic acid or the galvanocautery was that the diminution in the size of the tonsil was followed by irregular contraction with narrowing of the orifices of the crypts, out of proportion to the diminution in the size of the lumen near its base. Such contractions might not prevent the incarceration of detritus. The author consequently employed silver nitrate solutions ranging in strength from 4 to 8 per cent., making the injections every five to eight days. The amount of reaction had depended on the strength of the solution and had varied from slight to severe pain. Under this plan progressive diminution of the tonsils had taken place and the results had been gratifying. In one case the organs were reduced to one-quarter of their former size. A blunt strong needle such as was used by dentists for injecting gums was the best one to use. It might be straight or curved. Dr. Goodale believed that the effect of the silver was, theoretically at least, in harmony with the normal process of retrograde metamorphosis of the organ, in that it was a sclerosis proceeding from the base to the periphery and led to a symmetrical diminution in the size of the crypts.

Hemorrhage Following Quinsy; Ligation of the Common Carotid Artery; Recovery; with a Study of Fifty-one Cases of Hemorrhage in Connection with Pharyngeal Suppurations.—Dr. James E. Newcomb of New York City read a paper with this title. His patient was a man of 55 years, seen in consultation with Dr. J. D. McBarron. He had had quinsies all his life, but an immunity for the past ten years. The attack in question came on without any special features and on the fourth day the presence of pus was evident, and it seemed to be located rather far out in the soft palate. The patient's kidneys seemed to act well, but there was distinct arteriosclerosis. Incision of the quinsy was followed by escape of healthy pus and almost immediate bleeding. The latter was easily checked, but recurred several times, and finally became so profuse and persistent that a radical measure was deemed necessary. It was impossible to locate the bleeding point and the condition of the parts involved rendered any plan of suturing out of the question. It was found that the ulcerative process had worked backward and that the soft palate had perforated. Ligation of the common carotid artery was decided on and was done by Dr. C. N. Dowd. Recovery was without incident. No disturbance of cerebration resulted. Dr. Newcomb had found fifty additional cases reported in which hemorrhage occurred in connection with suppuration in the pharynx. Of this number forty-one occurred in connection with quinsies. They might be classified as follows: (1) Spontaneous opening of the abscess, with immediate hemorrhage, 11, with 7 fatal and 4 recovering; (2) spontaneous opening, with secondary hemorrhage, 15, with 8 fatal and 7 recovering; (3) opening by incision, with immediate hemorrhage, 7 cases, with 4 fatal and 3 recovering; (4) opening by incision, with secondary hemorrhage, 8 cases, with 4 fatal and 4 recovering. In addition there were 5 cases following retropharyngeal abscess, with 2 fatal and 3 recovering; 3 cases in connection with scarlatinal suppuration, 1 fatal and 2 recovering, and 2 cases in connection with gangrenous tonsillitis, both fatal. Summarizing, there were 51 cases, with 23 recoveries and 28 fatalities, or 54.8 per cent. Operations had been done as follows: Ligation of the common carotid, 16 times, with 11 recoveries and 5 deaths, once of external and internal carotid with recovery, and once of all three vessels with recovery. Two points were considered in detail by the author, first that relating to the invasion of vessel walls by suppurative processes. For a long time it was not believed that such a thing happened, but now it was universally admitted. In the case of quinsies the sudden diminution of pressure of confined pus when rupture of the abscess took place (or incision was made) on a weakened arterial wall, might lead to immediate rupture of the latter. In the second place we had to consider the differential diagnosis of swellings in the tonsillar region when accompanied by evidences of inflammation. We might have simple inflammation, tonsillar tumor, or aneurysm. The choice of operation would depend on our diagnosis. Autopsy records had shown that in the class of cases considered in this paper the internal carotid had often been involved. Ligation of the external carotid alone would not be sufficient to check bleeding. The dangers of ligation of the common carotid were not to be overlooked, but they were to be met according to the rules of surgery.

Dr. W. E. Casselberry thought that more stress should be laid on the dangers of ligation of the common carotid. It was disastrous to ligate the vessel for hemorrhage and get a paralysis of the opposite side. While the emergency named in Dr. Newcomb's paper had never occurred in his own experience, he had always thought that ligation of the external carotid would suffice as it did in tonsillar hemorrhage.

Dr. W. L. Ballenger said that he had learned by experience that in dissecting tonsils if we avoided injuring the musculature of the pillars and of the bed of the tonsillar fossa, we would not have severe hemorrhage, but if we did injure these structures, severe bleeding was apt to follow. In opening quinsies he separated the anterior pillar as if he was going to remove the tonsil and then by pushing the pillar out of the way and separating it from the superior constrictor muscle, the abscess could be located with accuracy.

Dr. J. O. Roe preferred the Hilton Fagge method of opening these abscesses with curved scissors and never used a knife.

Dr. Newcomb, in closing, said that the question of danger to brain integrity in ligating the common carotid was the same, no matter for what emergency this operation was done. The autopsy records in the material collected by him showed in several instances the internal carotid was the vessel which had been perforated. Ligation of the external carotid in such cases would be useless and he again emphasized the fact that the conditions in suppuration and after ordinary operation for tonsillotomy or tonsillectomy were entirely different. In one case we were working in healthy tissue, notwithstanding the hemorrhagic complication; in the other we were working in tissue which had lost its vitality and to which the application of styptic measures was conditioned by this fact. In an ordinary post-tonsillotomy hemorrhage, the bleeding site was often visible, but this was not the case in hemorrhages in connection with pharyngeal suppurations. There was no objection to a primary ligation of the external carotid, but it would not always stop the bleeding.

At the executive sessions of the Congress the following gentlemen were admitted to membership: As Corresponding Fellow: Dr. Gustav Killian of Freiburg, Germany. Active Fellows: Dr. J. F. Barnhill of Indianapolis, Ind.; thesis, "Some Essential Principles in the Surgery of the Accessory Sinuses"; Dr. B. Alexander Randall of Philadelphia; thesis, "Some Neglected Points in the Anatomy of the Pharynx"; Dr. Harmon Smith of New York City; thesis, "Multiple Papilloma of the Larynx in Children"; Dr. J. Gordon Wilson, Chicago; thesis, "A Study in Variations of the Frontal Sinuses with a Note on the Topography of the Cribiform Plate."

The following officers were elected for the coming year: *President*, Dr. A. Coolidge, Jr., Boston, Mass.; *First Vice-President*, Dr. Emil Mayer of New York City; *Second Vice-President*, Dr. Francis R. Packard, Philadelphia; *Secretary and Treasurer*, Dr. J. E. Newcomb, 118 West Sixty-ninth street, New York City; *Librarian*, Dr. J. H. Bryan, Washington, D. C.; *Member of Council*, to serve four years, Dr. H. S. Birkett, Montreal, Canada; *Delegate* to the Triennial Congress of 1910, Dr. W. K. Simpson, New York City; *Alternate*, Dr. J. H. Bryan, Washington, D. C. The Congress of 1909 will be held at Boston, the date to be determined by the Council.

Cystic Mastitis and Mammary Carcinoma.—G. Verga, after examining twenty cases of cystic mastitis found that in five there was evidence of carcinomatous metaplasia. He concludes that cystic mastitis presents itself under various forms; in the first connective tissue inflammation predominates; in the second there is proliferation of the epithelium in its different varieties, acinous, papillary, and adenomatous. The second form is frequently associated with cancer, which becomes implanted on the mastitis. Clinical examination is not sufficient to make a diagnosis of metaplastic carcinomatous mastitis. An accurate histological examination is necessary to establish the diagnosis. The surgeon should always be on the look out for the transformation of a cystic mastitis into a carcinoma.—*La Riforma Medica.*

TUBERCULOSIS OF THE EAR.

By W. SOHIER-BRYANT, A.M., M.D.,

NEW YORK.

In these days of widespread popular and professional interest in tuberculosis every point in the course of the infection, every organ and tissue affected, and every symptom which can assist early diagnosis have acquired special importance. Heretofore the ear has not attracted as much attention as its importance in this connection warrants. The ear interests us not only because it may be the seat of tuberculous infection, but chiefly because it can give the first sign of an incipient pulmonary tuberculosis.

The etiology depends upon the entrance of bacilli into the tissues of the ear. The entrance takes place (1) via the tympanopharyngeal tube by direct extension from the pharyngeal mucosa, (2) by direct extension from the epimastoid lymphatic glands, (3) by metastases from distant points of infection. The predominating form of the etiology varies with the age. In the tympanic form a non-tuberculous infection may precede the tuberculous. In infants the lymphatic extension from the mastoid glands is the most common road of infection. In adults entrance of the bacillus via the tubal route is more common. The least common is the metastatic form. Tuberculosis of the ear is essentially an early complication of more general tuberculosis because the ear is in direct connection with the upper air tract which in the vast majority of cases is recognized to be the road of primary tuberculous infection. Aural tuberculosis occurs early in the course of the disease for two reasons. First by reason of the entrance of bacilli through the tympanopharyngeal tube and second because of the proximity of the mastoid to lymphatic glands which may become infected early because they are connected with the upper air tract. The tuberculous infection of the ear by way of the lymphatics is more common in young children because in them these glands are more subject to infection.

The clinical picture varies with the mode, seat, extent, and stage of infection. So far as the final stages of tuberculous ostitis are concerned it makes little difference how the infection has entered the ear, but the initial symptoms vary with the road of infection. The lymphatic invasion is at first a periostitis with later involvement of the subjacent mastoid bone and still later tympanic involvement. In the tubal route of infection the first symptom is otitis media which may exist for a time without tuberculous characteristics. In the metastatic infection the mastoiditis is the first symptom.

The characteristics of tuberculous otitis media are its insidious onset, with impaired hearing and tinnitus. Pain is insignificant. The membrane perforates readily; the discharge is thin, usually odorless, and only slightly purulent. Redness may be present or not. Febrile disturbance is slight. Later on the tympanic membrane melts away and the perforation of the membrane increases in spite of ordinary treatment. There may be one, two or three simultaneous perforations of the membrane. The membrane continues to melt away, leaving the malleus hanging free of all membrane attachment; the ossicles become loosened and fall out and the discharge increases with the ulcerating area. Granulations are conspicuous by their absence. Finally there is complete tympanic destruction with abundant thin discharge. The tympanic walls become necrotic and sequestræ are formed after involving large parts of the labyrinth and petrous pyramid. Facial paralysis is a noteworthy accompaniment of this form of advanced aural tuberculosis.

Characteristics of the lymphatic infection are at first enlargement of the lymphatic glands of the mastoid region; next an infiltration of the epimastoid tissue usually without redness and with little tenderness. Later the periosteum becomes thickened. The general swelling increases. The outer table of the mastoid process is invaded. Softening and suppuration of the cold abscess type with comparatively slight pain and reaction occur and suppurating sinuses are formed. The tympanum is early invaded.

The characteristics of the mastoid form of tuberculous ear infection are that the signs of mastoiditis precede the tympanic or epimastoid changes. Its course is the same as described for the epimastoid infection except that the bone changes are here the first symptoms.

Resolution of the tympanic inflammation may occur spontaneously or after general treatment aided by appropriate local measures. As the tympanic appearances fluctuate with pulmonary tuberculosis they are a very good index of its course. An absolute diagnosis of tuberculosis is made on the tympanic appearances months before signs of tuberculosis can be found anywhere else.

The gross anatomy and histology of the tuberculous process in the ear are the same as in other parts of the body made up of mucous membrane, osseous tissue, and lymphatic glands. The two peculiarities which the ear has are, first that it is a multiple sense organ and secondly that in it the three tissues mentioned are very intimately associated. The bone is lined with a mucoperiosteum and the dura mater forms the inner periosteum. The cold abscess is the rule in ear tuberculosis. The softening and erosion of the mucous surfaces or periosteum and the disintegration of bone and the suppuration progress with little pain and redness or without much temperature. Though the presence of tubercular bacilli can usually be demonstrated in the pus and tissues, sometimes they are most difficult to detect. It is exceptional to find them in the thin secretion of the middle ear.

The clinical diagnosis must usually be relied on,

especially in the early cases. It depends on the peculiar picture which the middle-ear inflammation presents. One sees an indolent, serous or seropurulent, more rarely a purely suppurative, inflammation, melting away of the drum membrane, multiple or kidney-shaped perforations, exposure of the manubrium mallei, etc. Continuation of the ulcerative process in the face of ordinary treatment is pathognomonic of tuberculosis. Alternating decrease and increase of the activity of the process independent of obvious causes is always pathognomonic of tympanic tuberculosis.

It is probable that all the mastoiditis cases which begin with superficial inflammation on the outer surface are tuberculous and that tuberculosis is probably the cause of the severe mastoiditis occurring in infancy, just as it is the cause of the breaking down of the lymph glands. Glandular enlargement of the tragus or mastoid lymphatics always suggests tuberculosis if syphilis is excluded. Tubercle bacilli have been found in cases of otorrhea before tuberculous infection had been suspected. The differential diagnosis from syphilis is based upon the same differential characteristics found in lesions in other parts of the body.*

The treatment is fundamentally constitutional as it is in all tuberculosis. Local treatment of the tympanic form of infection is dry with especial care to cleanliness and the avoidance of all solutions. The powders which are most effective are pyoctanin and boric acid or iodoform. The treatment of the mastoid form is early and through operation.

Without treatment the prognosis of aural tuberculosis is for a continuation and gradual extension and for a development of a more general pulmonary tuberculosis sooner or later. With treatment the prognosis of the local condition is good for amelioration of the symptoms and for a final cure if operative eradication can be accomplished, if there is no other seat of tuberculous infection, or if the constitutional resistance can be increased to normal. When the ear tuberculosis is merely a complication of a more extensive involvement elsewhere, the ear prognosis depends on the prognosis for the more general infection. In the mastoid form of tuberculosis, prognosis is good after radical operation. The postoperative recovery is better than in nontubercular mastoiditis. The prognosis of the pulmonary tuberculosis may be made on the course of the middle-ear affection.

Case 12,016.—*Positive tuberculosis diagnosis made by the middle-ear symptoms five months and eleven days before the pulmonary diagnosis was positive.* Man, 32 years old, the picture of health and activity, with clear complexion, and high color, leading a very active business life. A more than moderate user of alcoholics, but not intemperate. August 20.—Three days previously he used a nasal douche, blew his nose, and infected the right ear. Acute otitis media followed with serous leaking the next morning. Drumming in the right ear for twenty-four hours; now high-pitched singing, sizzing, and ringing tinnitus and stuffed feeling in the ear. Tympanic membrane dark red, leaking serum. September 6.—Various forms of treatment have been used by others, among them myringotomy and bichloride of mercury syringing. There is now a purulent discharge and the mucous membranes are all dark red. Commenced dry treatment. September 9.—Politzer's acoumeter heard in the right ear at 27 inches. Low tone perception markedly impaired. High limit for tone perception 80,000 single vibrations. A little serum only in the tympanum. Free perforation of the drum membrane. Valsalva inflation goes through. September 10.—Politzer's acoumeter heard at 6½ feet. September 26.—Perforations reduced to a pin point. There was less congestion of the tympanum, which was nearly dry. The dry treatment of the ear soon overcame the damage done by the syringing. October 1.—Politzer's acoumeter heard at 9 feet. Perforation closed. Upper half of tympanic membrane red and a little bulging. October 4.—Small, invisible perforation; covered it with a paper patch. October 8.—Removed paper patch and found a little pus under it. October 15.—Perforation closed. High pitched ringing tinnitus and stuffed feeling still present. October 19.—Politzer's acoumeter heard at 15 inches. Ear looks better. October 24.—Politzer's acoumeter heard at 7½ inches. Perforation wide open. Tympanum dry; some dry discharge in meatus. October 29.—The ear is in a bad condition. Purulent discharge and perforation larger; it is situated at about the center of the membrane. Landmarks not visible. Tube clear as usual. A diagnosis of tuberculosis was made on the varying and resistant course of the tympanic inflammation. November 1.—Double perforation, one anterior and one posterior about the level of the umbo mallei distinctly seen. *Approaching tuberculosis of lungs positively prognosticated.* November 4.—Tympanum nearly dry. Perforations show no tendency to heal. November 9.—Tympanum dry. One perforation seems closed; the other smaller. Corrosive sublimate cotton dressing. November 12.—The cotton dressing removed; it was full of dry discharge. Perforation larger. November 19.—Double perforation again. Crust all over tympanic membrane. November 26.—Watch heard at 3 inches. Double perforation present. December 3.—Tympanum dry and membrane pale. Perforations smaller. Crusts on tight. December 10.—High pitched sizzing, ringing sounds have been constant from the beginning of the trouble. Hears occasionally very high pitched whistles. Perforations smaller. Watch heard at 2 inches. Noted that patient's fingers were all very much clubbed. December 17.—Watch heard at 5 inches; Politzer's acoumeter at 5 feet. Crust removed, then watch not heard. Only one perforation. Membrane dark red, especially above. Malleus getting drawn in by cicatrization. Patient perspires easily. December 23.—Politzer's acoumeter heard at 9 inches; watch heard on contact. Bone conduction in median line lateralized to affected ear. Perforation much enlarged; it is kidney-shaped, concave above, located below umbo. Promontory pale pink; rest of tympanum paler. January 27.—Patient writes that the ear is exactly as it was; no perceptible discharge; no especial feeling of discomfort; there is a clear aperture in the drum; the hearing is no better and no worse; "otherwise I am so busy now that it will be impossible to call as you suggest." February 6. Politzer's acoumeter heard at 15 inches. No discharge. Clean perforation. A scab in fundus of meatus. After wiping with cotton, Politzer's acoumeter heard at 11 inches. No change in weight. A little cough and expectoration in the morning. February 16.—Patient's wife says patient has lost weight lately. One brother died of tuberculosis. Slight bronchitis found by family physician. February 23.—Politzer's acoumeter heard at 10 inches. Crust removed from perforation, then acoumeter heard at 8 inches. Tympanum red. Membrane

*Crockett, E. A.: "Tuberculosis of the Middle Ear and Mastoid," *Journal of the A. M. A.*, Vol. XLVII., 1906, p. 1293.

nearly all destroyed. February 28.—Patient writes that he is overwhelmed with work and feels first rate. March 7.—Typanum clean. Total destruction of tympanic membrane. Malleus bound tight on promontory. Attic cut off by a cicatricial curtain, but antrum and tube wide open. Singing and faint sizzing tinnitus. Politzer's acoumeter heard at 12 inches. Tympanum not as congested. Patient appears thinner and looks tuberculous. Color, hectic. April 8.—*Tubercle bacilli found in sputum.* In spite of repeated physical examinations by the family physician nothing more than the bronchitis had been detected. The cough had gradually increased of late. This worried his wife, but he never mentioned the cough to me, even denied it. April 29.—Patient left New York for Colorado. The patient could not be controlled; previous to the detection of tubercle bacilli, he made no alteration in his previous habits; even after the bacterial diagnosis until his departure for Colorado he made little change in his habits except more careful and extended diet.

Case 14,548.—*Tympanic tuberculosis complicating pulmonary tuberculosis; shows fluctuations of the tympanic inflammation coincident with changes in the general condition, the advantages of dry treatment, especially with pyoctanin in the tympanum, and the marked constitutional improvement on relieving the distress caused by the ear.* Ear trouble began September, 1903, some months before the pulmonary tuberculosis appeared. The patient has been in a tuberculosis sanatorium off and on since September, 1904. Before I saw the patient he appeared to be almost if not quite cured of his pulmonary tuberculosis. Then the tinnitus began, nearly driving him crazy. In spite of the sanatorium treatment he lost ground rapidly. Man, aged 27 years. November 7, 1906.—Right ear; the drum membrane looked cicatrized, flat, and cloudy. Left ear was full of some foreign substance, suggestive of blood and epithelium; it was wine-colored, softish, looked like raisin skins, and had a fruity odor. Cleaned ear out; no sign of pus or discharge. Anterior inferior quadrant of drum membrane perforated. Thick mucus in tympanum. Canal red. Dry treatment; boric acid. Patient complains bitterly of exasperating and varied tinnitus. Has lost weight of late. Can do nothing, the noises are so bad. Dr. G. S. Dixon made the following pathological report on the material taken from the meatus of the left ear: "Squamous epithelium held together by dried cerumen and cemented by dried serum. The amount of cerumen is small." November 21 patient writes: "Last week was very trying. The noises in the ears were terrible and in consequence I became nervous, overwrought, and unable to sleep at all and my head feels as though it were in a vise. November 23.—Left ear again full of fruity, ill-smelling substance. November 26.—Involvement of left lung, anteriorly and superiorly. Weight, 140 pounds. December 4.—Lungs better. Left ear has a clean meatus. Thick scab on edges of perforation, which is large, occupying lower third of membrane. Tube clear. Removed scab and relieved tinnitus. Patient says the tinnitus was relieved for a few days after the last treatment. Note the constitutional gain following the improvement of the ear. December 8.—Tinnitus much better. Small crust had reformed. Lungs improving. Dry treatment; iodoform. December 13.—Perforation contracting. December 18.—Ear discharging a little mucus. Dry treatment; boric acid. January 7, 1907.—Ear good until a week ago, when the patient "took cold." Now profuse seropurulent discharge. Destruction of lower half of membrane. Tinnitus does not bother patient now. January 11.—Discharge stopped after last visit. February 1.—Ear discharging a little. Dry dressing; boric acid. February 9.—No discharge. Perforation reduced in size. Valsalva inflation positive. February 22.—Tympanum contains clear fluid, consistency of saliva. February 27.—Much yellow, ropy fluid in tympanum. Dry treatment; xeroform. April 1.—Tympanum full of fluid. Some granulations in superior posterior region of tympanum. General tympanic surface uneven and a little dirty. *Diagnosis of aural tuberculosis* is made on the resistant, fluctuating, and progressive course of the tympanic inflammation. The perforation occupies nearly the whole of the tympanic membrane. Watch heard at 4 inches. Tube open. April 8.—Tympanum full of thick mucus. April 12.—Ear has been discharging a good deal. Dirty gray fundus of perforation. April 17.—Discharging a little more. April 27.—Discharging yellow, syrupy mucus. Patient makes an objective pharyngeal tinnitus snapping by movement of tubal mouth; this can be heard at a great distance and is very annoying to the patient. May 13.—Much exfoliation of epithelium in tympanum. Watch heard at 11 inches. May 21.—Less discharge, but more epithelium. May 28.—Looks well. Much epithelium in ear. Tinnitus and discharge annoying for two days. June 8.—No discharge, but tympanum damp. Pyoctanin insufflation. June 24.—Cleaner than usual. Pyoctanin. July 7.—Tympanum dry and cleaner. Some desquamated epithelium in ear. July 20.—Tinnitus less. Tympanum dry. September 9.—Tympanum damp; no discharge. Pyoctanin. October, 1907.—Weight, 156¾ pounds. Dullness the same. No elevation of temperature while in the sanatorium. October 12.—Tympanum moist; no discharge. Pyoctanin. November 26.—Very little tinnitus. Ear dry. Watch heard at 1 1-4 inches. January 2, 1908.—The right ear discharged a few days ago and loud tinnitus. Canal full of fetid detritus. No perforation detected. Left ear slightly fetid, serous discharge. Slight epithelial exfoliation. Pyoctanin in both ears. January 11.—Ears fairly clean; both moist. Pyoctanin. January 18.—Right ear, membrane clean and bright. No perforation. Left ear, a little yellow serum in tympanum. Pyoctanin. February 1.—Lungs about the same. Weight, 158½ pounds. Temperature had continued normal. February 8.—Slight tinnitus in both ears. Left ear, a little yellow pus at fundus. March 7.—Gaining weight fast. Began to gain three months ago, when he went back to sanatorium after a loss of weight while at home. Ears not so noisy. Left ear, dry and pretty clean; there has been no discharge. Watch heard at 2¾ inches. Right ear looks very well. Watch heard at 26 inches. March 28.—Very little annoyance from left ear. Dry, clean, and white. Moist tubal râles. Pyoctanin. Right ear all right. April 18.—Tinnitus annoying. Right ear clean. Left ear blue at fundus. Pyoctanin. No discharge. Entire loss of the tympanic membrane, which has melted away. The manubrium mallei stands out clear without cicatricial adhesions, which all have melted away. Signs are still present in lungs. May 2.—As before, excepting the loss of the lower fourth of the manubrium mallei. May 4.—Involved area of lung has decreased from the eighth to the sixth rib. Still has normal temperature; weight, 163 pounds.

Summary: Tuberculous invasion of the ear is primary or secondary. Primary invasion is direct through the Eustachian tube or through the mas-

toid lymphatics. Tympanic tuberculosis is a very early sign of a more general infection. It also gives an accurate indication of the course of a concomitant pulmonary tuberculosis. Tuberculous mastoiditis has similar characteristics to tuberculous inflammation of other bones. Prognosis for the ear tuberculosis is good with proper hygiene and local treatment, and early through operative treatment in cases of bone involvement. Pyoctanin dry treatment is the most efficacious for tympanic tuberculosis. The evil effects of a tympanic tuberculosis may cause pulmonary tuberculosis to take a lethal course.

57 West Fifty-third Street.

THE CHEMICAL RAYS PROMOTERS OF LIFE AND ENERGY: THEIR MODE OF ACTION, AND THEIR THERAPEUTIC USES.*

By MARGARET A. CLEAVES, M.D.,

NEW YORK.

"The daily tribute to the sun
Lives on, in tree and fruit and flower;
Lives on, with subtle change of power,
When the last hour of the day is done.

And what kindly sun has given,
Reborn in many a varied form,
Is in the wind, the sea, the storm
And when the lightnings flame through Heaven."

In this little verse, a tribute to Friendship† from the pen of that gifted writer Weir Mitchell, is embodied infinite scientific truth.

Many years ago an earlier poet sang in "Lallah Rookh"

"Sunshine, though broken in the rill,
Though turned aside, is sunshine still."

Both have typified in their verse the transformation of the Sun's energy. To the living organism it bears the same relation as to "tree and fruit and flower", and the chemical rays existing abundantly in the solar spectrum are verily the promoters of life and energy.

Experiment and observation have confirmed the doctrine of the correlation of forces and the conservation of energy, and one by one the different classes of energy which present themselves in terrestrial phenomena have been traced to their solar origin. This familiar truth of the transformation of energy, is too little heeded by us in our daily professional life.

We expose the body superficies or some portion of it to the action of light, radium, the Roentgen ray; we utilize some one of the various manifestations of electrical energy, we exhibit drugs, inject serums, ferments and antitoxins, use our mental force or magnetic power in psychical suggestion or control, but how often do we reflect that we are simply using energy of a given kind which is being transformed into the physiochemical energy of life.

Whatsoever we bring to our aid, whether the forty or fifty drugs which have stood the test of time, whether physical measures or psychical suggestion, energy is transformed, and by this transformation physiological conditions are stimulated and established to a degree of more or less completeness according to the extent of impairment and the time, degree and care with which therapeutic measures are used. It is only by discriminating analysis and weighing of the observations and results of the well grounded physician and skilled therapist and by superimposing the fundamental knowledge of the physics and physiological action of the measures used that medicine can advance to the exactitude of a science.

The daily use of light clinically for fifteen years, especially light rich in the chemical (blue indigo and violet) leads me to regard it as an agent of no small import in the many chronic perversions of physiological action requiring medical care and emphasizes my confidence in it, a confidence first inspired by its known relation to life.

In whatever I bring forward as to its value, I wish it distinctly understood that neither light nor electricity are used to the exclusion of other measures, nor on the other hand are these used to the exclusion of drugs, serums, ferments, psychical suggestion, and above all the most careful directive and educative work in matters of diet, hygiene, and sanitation.

Chemical action is not confined to frequencies of short wave length, any more than thermal action is confined to the frequencies of the red region.

Under suitable conditions the green, red, and infra red will produce photographic action. The only physical distinction to be made between light rays, heat rays, and actinic rays is that of wave length.

By reason of the different wave lengths a different action upon the living tissues takes place; it is with the component parts of the structure, as it is elsewhere in the physical world, the effects are those of heat, light or chemical action according to the state or condition of matter upon which the energy from the sun or an artificial source is radiated.

Radiation does not leave the sun nor an artificial source as heat, but as radiant energy. The wave lengths within certain limits fall upon the eye and they are called light; the same wave lengths will decompose the silver bromide of a photgraphic plate, hence they are called actinic rays; while equally well they will raise the temperature of a blackened thermometer bulb, therefore they are heat rays.

It is because of these physical facts that physiological action is stimulated and therapeutic results are secured in different degrees by the use of the various light mechanisms at the command of the physician.

The chemical rays of light are not used to the exclusion of the more purely thermal rates of vibration, but it is the former which are to be regarded as the promoters of life and energy and which yield the most profound and greatest range of therapeutic results. Purely chemical or cold light is used to the exclusion of the thermal rates, as, for example, in the Finsen method, or in the use of ultra-violet energy. Even so heating effects are produced.

The relation of life to light is so primary and intimate, and its power to produce physiological stimulation so great, that no matter what the source of light used, result will follow. Despite this truth, however, that source of light and arrangement of mechanism should be used which will tend to secure the best effect.

In a consideration of the subject of light the solar spectrum is the basis. It affords a greater quantity of energy of the blue-violet region than any artificial light and is very rich in ultra-violet at its source but fortunateiy the latter rates are largely absorbed by the atmosphere in transit from the sun. While the solar spectrum as a whole yields the maximum energy requisite to life and therapeutic result it is impractical to depend upon it for the latter where concentrated and well localized applications are essential, especially in northern climates and crowded

*Read before the New England Electro-Therapeutic Association, Boston, June 12, 1908.

†Dr. S. Weir Mitchell, *Everybody's Magazine*, April, 1908.

cities. In the electric arc, there is to be had a miniature sun, giving more of the very valuable chemical energy of the blue-violet than any other artificial light. It is always available wherever there is electric power, lending itself readily to therapeutic needs, and at the same time with proper adjustment of mechanism yielding an abundance of ultra-violet energy which can be used very near its source.

On the other hand incandescent lamps of varying candle power, single or in groups, likewise yield blue violet or chemical energy, but to an inconsiderable extent as compared to the electric arc. With an increase in candle power requiring heavier wiring and more amperes than the ordinary incandescent light circuit there is increased spectral energy, which means an increase in the blue violet. If an incandescent light were rich in ultra-violet energy, as it is not, this energy would still be unavailable on account of the glass enclosing bulb.

Spark light, however, from a static machine or coil is rich in ultra violet energy, and spark lamps with quartz lenses afford these energtic short waves in abundant quantity. They, however, lack in quantity the penetrant energy of the blue violet.

The light of vacuum tubes, energized either by means of a coil or static machine, is also chemically active, but the glass enclosing bulb while prohibiting the passage of the ultra violet permits that of the blue violet.

To secure the best physical action and therapeutic result, a source of light which yields a complex of all the frequencies, especially an abundance of the penetrant energy of the blue violet, should be chosen, for quantity is essential.

The physical action of light is comparable to that of the constant or galvanic current. In my use of light and especially the light of electric arcs of from 10 to 80 amperes I have constantly been impressed with the similarity of observed action and result from the use of light and that of the constant current. The one acts equally well with the other in many conditions. This is true however of all our directive and corrective physiological stimuli.

It is ninety years since Grotthuss formulated the two laws of light which fundamentally account for its catalytic actions: (1) Only those rays of light which are absorbed can produce chemical action. (2) The action of a ray of light is analogous to that of a voltaic cell.

It is therefore in accord with physical facts to compare the action of light with that of polar electricity (constant or galvanic current). It is the accumulation of the products of electrical decomposition at the poles which differentiates the use of the one from the other in definite morbid entities. Grothuss' conception of light and his conception of photo-chemical processes as electro-chemical ones were largely brilliant prophecies which to some extent are only now receiving their scientific confirmation and experimental foundation. In a series of papers on the electro-chemistry of light, Wilder D. Bancroft* points out that in many instances it would only take a slight change in the wording to make the work of Grothuss quite modern. Instead of saying as Grothuss did of the decomposition of silver by light, that the silver combines with the +E of the light, the electro-chemist of to-day would say that in the electrolysis of a silver salt the positively charged ion is converted into silver rather by losing its positive electric charge or by having the positive electric charge neutralized by a negative charge.

The E. M. F. of light is very low indeed. But the tissues of the living organism in health lend themselves to the action of radiance, are, so to speak, transparent to them and therefore a high E. M. F. is non-essential to characteristic action. Because of its greater E. M. F. and polar action the constant current influences more profoundly deeply seated and well organized inflammatory products.

The transference of the ions of soluble electrodes such as zinc, mercury, copper, and silver at the anode may be compared to the sensitization of the tissues by light sensitive substances as eosin.

In the chemical action of light we are dealing with phenomena analogous to the formation and decomposition of chemical compounds under the influence of the electric current.

It is a well known fact that the rays of the spectrum producing the greatest heating effect are not the rays of the spectrum which produce the greatest chemical effect. While it is true that all can and do produce chemical action depending upon the substances to which they are placed in relation, the rays which are most active chemically in relation to the living organism are the same as those active in the blackening of silver and are to be found at the upper end of the spectrum.

Chemical action, which is the highest form of vibrational activity, is best induced by the shorter frequencies of vibrational activity of the oscillating light frequencies. As the living organism is a chemism it is but rational that the most profound and deep seated effect should be produced by the highly chemical and penetrant frequencies of light vibration. Such is the case, although all the frequencies are necessary to direct and conserve the best physiological activities; likewise all lend themselves to therapeutic result, but not equally.

So far as light frequencies are absorbed they energize, for absorption means work accomplished. No energy is lost, and the extinction of energy in space or its absorption and consequent disappearance is one of nature's fundamental truths. When absorbed it is converted into other forms of energy of equal value. When the waves of light fall upon a growing plant work is done, and the green leaf absorbs all the frequencies of light except the green, which is reflected. In the light absorbing substance a transformation takes place, beautifully shown in the green leaf by the chlorophyll function.

In the unity of result secured by the use of electricity, radiant energy and the internal secretions in the promotion of nutritive processes there is a common action explainable on common ground, an action already foreshadowed and fundamental to cell metabolism.

It is not that we fail to obtain result from our chosen therapeutic measures, but that we fail to understand clearly the relation between the lack of chemical control in the living organism and the physiological action of the measure used. The physiologist Pawlow* of St. Petersburg has voiced the belief "that the world of pathological phenomena is nothing but an endless series of the most different and unusual combinations of physiological occurrences which never make their appearance in the normal course of life. It is a series of physiological experiments, which nature and life institute, often with such an interlocking of events as could never enter into the mind of the present day physiologist, and which scarcely could be called into existence by means of the technical resources at our command. Clinical observations will consequently always remain a rich mine of physiological facts."

*The Electro-Chemistry of Light. Wilder D. Bancroft. *Journal of Physical Chemistry*, April, 1908, p. 209.

*Pawlow: "The Work on the Digestive Glands," Thompson's translation, p. 46, 1902.

Of equal importance to the physiologist and the clinician are the problems of nutrition, respiration and tissue metabolism.

In so far as I have looked into the recent work of Sajous,* his deductions, it seems to me are worthy of recognition as a basis for physiological therapy. The principles which he has evolved from his analysis of all the known facts, are not new to the thought of the more advanced and best thinkers in the profession, but only now have they been logically followed to a conclusion in their threefold relation, physiological, pathological, and therapeutic. In their acceptance a rational explanation of the action, not only of the various remedies which are known to produce definite effect but of physical measures as well, is afforded.

The principles involved may be outlined as follows: It is not yet understood how stimulation causes the dilatation of blood vessels. All disorders are functional or organic, and function is impaired by all organic diseases. The function of the leucocytes is to convert the constituents of the ingested proteids into living proteids. The granulations of the leucocytes supplied to tissue cells are living substance.

The adrenal active principle endows the constituents of proteid with life. The white cells are highly organized, though diminutive secreting organs. By reason of the various ferments contained in them, each cell may, says Carles,† be regarded as a minute laboratory.

The correspondence between the chemical properties of adrenal extracts, adrenalin and other adrenal extractives, with those of the active principles of the oxidizing substances oxidase wherever found, experimentally shows that a ferment of which the active principle of the adrenal secretion is a type, is the active agent in the oxygenation process of all plants and animals.

The observations and experiments of recent physiologists‡ (Haldane and Smith) on mice, birds, dogs and other animals, they found that the normal oxygen tension in arterial blood is always higher than in alveolar air; and they were consequently led to conclude that the transmission of oxygen between the alveoli and the blood cannot satisfactorily be explained by mere diffusion.

The physiological function of the internal secretion of the adrenal is loosely to combine with the oxygen of the air in the pulmonary alveoli and to endow the blood with its oxygenating properties. To this internal secretion of the adrenals, Sajous has given the name of adrenoxidase, a term which embodies its origin, the adrenals, and its general distribution as suggested by oxidase.

The presence of oxygen saturation and alkalinity in the leucocytes is necessary to secure their staining by methylene blue. In this is found the proof of the presence of adrenoxidase, as it shows that they contain the oxidizing substance and blood salts. The presence of oxidase in leucocytes is also demonstrated by means of the guaiac test. The presence of trypsin and other ferments is recognized as a fundamental feature of phagocytosis. The dynamic element in the vital process is believed to be the adrenal principle.

A portion of the pancreatic ferments causes the formation of an intestinal secretion which passes through the splenic vein and into the portal system, likewise the splenic internal secretion.

*Internal Secretions and The Principles of Medicine. Sajous.

†Carles. Paris, 1904.

‡Haldane & Smith. *Journal of Physiology*, Vol. XXII., p. 231, 1897.

In the portal system the leucocytes absorb the pancreatic ferments and splenic internal secretions which they supply to the tissue cells and with which they carry on their intrinsic functions.

The nervous system in keeping with other tissues is composed of cells likewise developed and nourished by leucocyte granulations and traversed by the oxygen laden adrenoxidase. The myelin of nerves is not a nerve insulating material of sheath, but a compound rich in phosphorous which, when in contact with the oxygen-laden adrenoxidase circulating through them, generates nerve energy.

A thorough analysis of all the data anatomical, physiological, pathological, and therapeutic leads to the conclusion that the pituitary body is the general and governing center of the spinal system, which includes the gray substance of the base of the brain, pons, bulb of the spinal cord and the nerves derived from them. The anterior pituitary body is a lymphoid body, which through the intermediary of a center located in the posterior pituitary body, the upper dorsal sympathetic ganglion and the splanchnic nerves govern the functional activity of the adrenals.

The abdominal main path to the adrenals is the great splanchnic nerve. It is further concluded that the anterior pituitary body governs through the posterior pituitary body all of the oxidative processes of the body. The functional activity of the thyroid glands is also controlled by the posterior pituitary center, thus constituting the adrenothyroid center.

By the functional union of the pituitary body, adrenals and thyroid the adrenal system is formed.

In the higher mammals the rank of protective organ has been accorded to the pituitary body. It is reasoned from all the evidence in hand that one of the functions of the pituitary body is to detect any toxic substance that may be present in the blood and that it is the foundation of the organism's autoprotective mechanism. The thyroid and parathyroid secretions jointly form the opsonin and agglutinin of the blood; the adrenal system composed of the pituitary body, the adrenals and the thyroid apparatus constitute the immunizing mechanism of the body. It may be reasoned that as the adrenal system has for its purpose to protect the body against disease, that by enhancing the functional activity of the adrenal system we can overcome disease. Through the functioning adrenal system there appears in the blood and phagocytes an excess of autoantitoxin, a chemical homologue of diphtheria antitoxin and other antitoxins. This autoantitoxin, and all other antitoxins, is composed of the internal secretions of the adrenals, adrenoxidase; Ehrlich's amboceptor of the pancreas, trypsin; Ehrlich's complement of the spleen and leucocytes, nucleoproteid; and by the thyroid and parathyroid, thyroidase, Wright's opsonins. The increased bacteriolytic and antitoxic proportions of the blood and phagocytes are due to an excess of this autoantitoxin.

The role of heat center has been attributed to the pituitary and owing to a nervous connection with the adrenals which has been proven to exist, the adrenal secretion should be capable of raising the temperature when in excess in the blood. Physiologists have observed a slight transitory disturbance of the ratio of heart beats, also of the respiration and of the body temperature, under the effect of adrenal extractives. Removal of the adrenals and destruction of the pituitary body are followed by a steady decline of temperature until death results. Jacques Loeb has predicted that through the oxidases one may be able to control life as the artist governs the keys of the piano.

From his very complete analysis of extensive data scattered throughout the literature bearing upon the science of medicine and illumined by his years of observation and experience, Sajous deduces the following facts:

(1) That adrenoxidase (the oxidases) is the agent through which life may be controlled.

(2) That it is the center of the adrenals in the pituitary body which, through the adrenals and their adrenoxidase-forming secretion, controls life.

(3) That the adrenal center is an organ having for its purpose to test the blood and protect it against the intrusion of noxious substances.

(4) That noxious substances introduced into the blood can, by provoking a reaction of the adrenal center, enhance the activity of metabolic processes.

(5) That inasmuch as we can therapeutically (all drugs being toxic as far as the test organ is concerned) increase or abate fever, we can also control tissue metabolism and its derangements.

(6) The test organ is therefore to be regarded as a keyboard through which we can "favor or retard the action of the oxidases," *i.e.* the vital process itself.

In the absence of other and more natural basis for our therapy it seems that we can do no better than to accept these conclusions of Sajous. If correct they will stand; if not, future research and observation will refute them.

To the therapist familiar with the physics of light and its physiological action as well as experienced in its use as a therapeutic measure, is afforded a clear and rational explanation of its mode of action as well as that of other measures.

In all uses of light the point upon which stress is constantly laid is in its enhancing the oxygenating power of the blood. In all my work with light, and in all my writing concerning it, this has been the constant theme. The hyperemia, superficial or more or less deepseated, secured as a result of exposure of the body superficies to light serves not only to render more active the sluggish circulation, to the relief of arterial tension, but serves as well to increase activity of the adrenal function. This would mean a pouring out of the adrenal secretion to combine with the body's oxidase forming the adrenoxidase, and through this agent physiological processes may be controlled. Better oxygenation of the blood means better respiration, better circulation, and better tissue respiration or metabolism and a better functioning control organ, by means of which each and every cell takes on physiological activity.

There is always secured by the body's exposure to the action of chemically active light, when intelligently prescribed and administered, a sense of warmth, quiet and wellbeing. Especially is this true of the electric arc. The stimulus thus imparted to the chemical activities extends its influence to the nerves and nerve centers, for after all they are fed in the same way by the circulation as other tissues.

May not the similarity of action and result in functional and to a certain extent organic conditions from the use of electricity, light, *x*-ray, radium, in a word radiant energy, and the internal secretions be due to the ability of all these agents when used within physiological limits to stimulate ferment action, the same stimulus which is secured by the exhibition or injection of suitably selected internal secretion preparation. The sun gave life and the sun perpetuates life—without it we should not continue our existence. All glandular activities have to do with the ferments upon whose integrity depends life, and the therapeutic aids which minister to this integrity command our earnest attention. There is much shadowed forth in this connection to which I do not wish to give expression, because the proof at hand does not warrant it. This is true, that all about us, close at hand lies a wealth of unobserved and as yet unrelated fact, awaiting only the mind of the intuitive genius to tear aside the intervening filmy veil. Too strong sunlight is not good and in the tropics the skins of the people are densely pigmented to prevent hurtful effects. It is not irrational to believe that in this natural condition we have a wise provision of nature to prevent a destructive action upon the ferments. If the action of light is too strong, an inhibitory effect may be the result. In the time at command it is only possible to suggest these lines of thought for your earnest study and investigation.

The biological importance of the chemical rays has been fully established by a host of conclusive experiments. They are absorbed, they energize. Absorption means work accomplished and this work in the living organism is the direction of the chemical processes necessary to life and energy.

It is easy to follow the further rationale of their action according to this interpretation of physiologic action. The degree of result obtainable from their use must of necessity depend upon our correct reading of the conditions to be treated, as well as our technique and dosage. The malarial plasmodium is deprived of white light by reason of the opalescent qualities of quinine. It is easy to understand, therefore, why quinine is the remedy in malaria, and why sunlight is bad. The blood cell, so to speak, is shadowed from light by the characteristic flourescent properties of the specific drug.

The range of effects from radiant energy are from life to death—from light to dark. Injury may come, death may follow or reversion to physiological processes may be secured. Therapeutic result, however, is far more frequently obtained than damage done.

Résumé: (1) The chemical frequencies of light are the promoters of life and energy.

(2) Thermal are never used to the exclusion of chemical frequencies in light therapy.

(3) Chemical frequencies are directive or destructive according as they are used. Especially is this true of the irregular disorderly impulse of the *x*-ray as compared with the rhythmic energy of the visible spectrum.

(4) The *x*-ray and radium radiations are of great value in many skin conditions, even superficial epitheliomas, in some instances mitigating the symptoms and staying the progress of deep seated malignant processes as well. They are, however, on the other hand capable of exciting malignancy and inhibiting physiological function.

(5) Bactericidal energy has been located by experiment in the middle third of the ultra violet region. Skin reaction is established by ultra-violet energy.

(6) The best results are secured in deep seated well organized skin lesions by a complex of the penetrant blue-violet and ultra violet.

(7) Where profound sudation is desired over and above penetrating effects, a source of light affording thermal with a minimum of chemical energy is indicated.

(8) When deep seated effects are desired, sources of light rich in blue, indigo, and violet are indicated.

(9) The spectra of the different sources of energy vary in degree not kind; hence the interlocking of effect secured and result established from the various light sources.

(10) When the office equipment affords but one light mechanism preference is yielded the electric

arc as providing the maxima of energy required in initiating and establishing necessary physiological processes whether the departure from the normal is characterized by a skin expression or not.

(11) More or less profound hyperemia is established as a result of the use of light, depending upon its length of application and the degree of penetrating power. Upon this depends the rationale of its action.

(12) The physiological action of the chemical rays is fundamental to nutrition.

(13) The chemical rays are an invaluable therapeutic adjunct in the host of chronic conditions characterized by loss of chemical control; they lend themselves to conditions of malnutrition or perversions of nutrition, to both simple and secondary anemias, controlling hemorrhagic conditions associated with the latter, as uterine and rectal, for example. They are almost a specific in the annulment of pain, relieving for a time even that from pressure of malignant growths, quieting and steadying nerve action in simple nervousness, storing up energy for the neurasthene, establishing more or less hyperemia in organic cord conditions and to that extent holding and preventing extension of the disease, contributing alike to the relief of a simple depression or excitability and to a maniac-depressive insanity. They are likewise effectual in absorbing effusions from serous cavities and subcutaneous structures, whether secondary to malignant processes, an inflammation, a leaky heart or a hydrocephalic effusion associated with rachitis. They also prevent and cut short the progress of infective processes, and cure or improve the many skin expressions of disturbed metabolism. Equally they may arrest and control respiratory disturbances from a simple catarrhal cold to a bronchial asthma or a pulmonary tuberculosis. They are in short an agent of infinite value either alone or supplementary to other measures when intelligently directed and skilfully applied. In an office affording every luxury of equipment, I feel that of physical measures the constant current and electric arc contribute very largely to the securing of therapeutic result.

CUGUILLERE'S SERUM IN THE TREATMENT OF TUBERCULOSIS.

By EUGENE CARAVIA, M.D.,

NEW YORK.

Ever since Jaccoud, in a series of lectures published in 1881, proclaimed the curability of pulmonary tuberculosis in all its stages, a general endeavor to find a curative treatment for the white plague has occupied the minds of scientists all over the world. It seems, though, that notwithstanding the great advance in the knowledge of tuberculosis, its treatment has not made much progress. Jaccoud's general outline of diet, hygienic measures, aërotherapy, and hydrotherapy is still in vigor, and, with but few modifications, is the Credo of the majority of practising physicians, who have practically discarded the long list of drugs and the various tuberculins and sera.

Have we gone back to the pessimism of Laënnec, who wrote that "the cure of tuberculosis is possible for Nature, but not for the physician"? Are we, like the nomadic populations, to depend entirely on the influence of the sun and the moon and the air, and some symptomatic palliative remedies? Is the physician to abdicate the rôle of a therapeutist?

The following description of Dr. Cuguillère's serum may give a negative answer to all those questions; and notwithstanding the fact that some cases of pulmonary tuberculosis may owe their cure to diet and fresh air and sun, and some others to this or that other drug, to this or that other tuberculin or serum or method of treatment, Dr. Cuguillère's serum is the only one thus far which has stood severe and most scientific experimental tests on animals, and the only one which has given the most constant and positive clinical facts.

Dr. Cuguillère's vegetable serum is in the ninth year of its existence. Its principle is based on Koch's writings, who in order to conquer tuberculosis set himself the task of solving three propositions: (1) Determine and cultivate the pathogenic agent of tuberculosis; (2) Find out and classify all the agents able to attenuate its culture or to kill them *in vitro;* (3) Find out a way to obtain the same effects in the animal and human organism.

Everybody knows how successful he has been in the first proposition by determining the staining reaction and cultivating the bacillus known by his name. To solve the second and third propositions, Koch used successfully, but *in vitro* only, physical (heat, light, electricity) and chemical (acid bases) agents. But those agents could not be used in living beings.

Another line of experimentation brought Prof. Koch to use a certain number of metals which have the power to kill rapidly and surely the cultures of *B. tuberculosis.* Rollin found that a nonoxidizable metal without radioactivity, like platinum in metallic state, will totally prevent the development of *Aspergillus niger.* Koch found that cultures of *B. tuberculosis* are killed in the presence of even an infinitesimal solution of the salts of gold. Other metals exhibit the same properties. Metalloids, like sulphur, chlorine, iodine, bromine, are as much, if not more, active.

But those agents also have been found without action on the bacillus in living organisms. "A healthy organism," says Cuguillère, "tolerates with difficulty the absorption of metallic salts. An organism infected with tuberculosis is not able to retain those necessary for its own defense. It demineralizes itself, and, consequently, it seems impossible to assimilate new ones."

Then Koch abandoned this line of investigation and declared that tuberculosis would be curable by the introduction into the organism of an organic remedy, hence his new researches on products elaborated by the tubercle bacillus.

Cuguillère agrees with the opinion that tuberculosis could be cured by a living serum, but he thinks that instead of toxins and antitoxins, this serum can be made to carry colloidal metals already assimilated, that have become organic, living, and possessed of their maximum activity. Consequently, it is the mineral and vegetable kingdoms that furnish the active principle of his serum, that is, organic sulphur taken from fresh juices of Brassica, Allium, watercress, horse-radish, and other herbs known and for many years used as antiscorbutic and antirachitic remedies.

Cuguillère's serum is a yellow liquid having a strong odor of garlic. It produces a burning sensation which disappears a few minutes after the injection. Its formula as given at the Congress of Tuberculosis in Paris, is:

Allylum sulphide,* 1.0; 1. Tincture of myrrh, 1.0; 1. Hayem's glycerinated serum, 100.

It is not possible to give in an article of this kind a detailed description of all experiments on animals and of all cases of human tuberculosis treated with

*The synthetic allylum sulphide is inactive.

Cuguillère's serum. It will suffice for our purpose to give a summary of some of them, taken from the writings and communications of Dr. Cuguillère at the Medical Congress held in Biarritz in April, 1903, the Congress of Tubereulosis in Paris in 1905, and the Société d'Applieation des Sciences Médicales, 1906, of Dr. Faure in Le Progrés Véterinaire of 1905 and 1906, of Drs. Escoyez and Cuvelier of Belgium, Dr. Carcano of Milan, Dr. Cutiliero of Lisbon, at the International Congress in Paris in 1905, and the International Congress of Medicine, Lisbon 1906, supplemented by a few personal cases.

The experiments on animals took place under the direction of V. S. Faure at the Chateau de Savignac sur l'Isle (Gironde, France), the property of the Marquis de Castellane, who is in the habit of submitting to the tubereulin test all bovine animals thirty days after buying them, in order to eliminate from his dairy all diseased ones.

1. Holstein cow, 8 years old, deficient general condition, very thin, with dry skin adherent to the ribs, dry cough. Resp. 48 a minute, rectal temperature 38° 6 to 38° 9, lymphatic glands on the sides, four times their normal size, hard, rolling under the finger, indolent; intermittent meteorism, obstinate diarrhea, nasal mucosities scarce; percussion on the ribs provokes coughing and signs of distress, kidneys sensitive to pressure; auscultation reveals the symptoms of double pleurisy at the lower parts; the middle and superior parts of the lungs present certain points with diminished vesicular murmur, others where it cannot be heard at all, while in others the murmur is increased, hard; ambulant sibilant râles. Rectal exploration reveals an increase in size of mesenteric glands. Diagnosis, pulmonary and glandular tuberculosis. Diagnosis confirmed by an injection of tuberculin. Condition aggravated three weeks later when another injection of tubereulin gives a reaction of 2.3°. After the first injection of 20 c.c. of Cuguillère's serum the temperature fell to normal and the appetite improved. Weekly injections of the same serum were given in doses varying from 20 to 50 c.c. for six weeks. At the end of that time there was no reaction with tuberculin; average temperature was 38.7° C.; notable general improvement; glands on the side reduced to almost normal size; coughing rare, resp. 20. Vesicular murmur a little harder than normal, excellent appetite, perfect digestion. Nothing abnormal in the size of the mesenteric glands. Injections of serum were continued three months longer. No reaction with tuberculin; increase in weight 75 kilograms. The animal seemed cured. It was decided to kill the animal to determine its condition.

Autopsy.—Sublingual and bronchial glands present a normal aspect; mesenteric glands show evident traces of cured tuberculous lesions, the cicatricial tissue contains encysted fine granulations of a very clear yellow color, calcareous, identical with calcified tuberculous granulations. Lungs, only some light foci of pneumonia. Absolutely nothing on the pulmonary pleura. Parietal pleura shows remnants of pleurisy, with here and there some filaments, small floating shreds of fibrous appearance and grayish-white color; but these were not considered as the remnants of tuberculous pleurisy.

2. A second cow with a fistula from a tuberculous abscess near the parotid surrounded with lymphatics, forming nodulous strings; enlarged sublingual, prepectoral, and superficial glands also in the abdominal wall. Cough, resp. 130, sibilant and mucous râles, slight pleuritic friction, cavernous murmur on the left anterior lobe; very decided diffuse dulness on percussion except anteriously on the left, where exaggerated resonnance almost tympanitic is found. General condition bad. Tuberculin reaction positive. Treatment with Cuguillère's serum weekly for three months—10 to 80 c.c. Owner cannot keep the animal isolated, and decides to kill it.

Autopsy.—Lymphatic glands normal in size, presenting on incision some rare yellowish granulations. Pleural adhesion on the left pulmonary lobe, of the size of a 10-cent piece. On the pulmonary pleura, patches the size of a 50-cent piece to the width of the palm of the hand, transparent and smooth, elevated only ¼ to ½ millimeter above the surface of the pleura; on incision the patches creak, have the aspect of fibrous tissue. On the parietal pleura those patches are more rare, smaller, and thinner. On the surface of the left anterior lobe are two patches 4 cm. in diameter, presenting in their centre fibrous filaments. On the corresponding parietal pleura are similar lesions but 1-3 smaller, which are the remnants of persistent adhesions ruptured at the time of the removal of the lungs.

The curative progress of the lesions was far more advanced in the pulmonary than in the parietal pleura, while in the first case the cure of the pulmonary pleura was more advanced. A transverse incision of the lung shows healthy pulmonary lobules that have never been invaded by tubereulosis; others show no trace of tubereulosis but are reduced to 2-3 their normal size. They are traversed by numerous bands of fibrous appearance; similar to so many pulmonary lobules which have disappeared, leaving a thick cellular tissue of fibrous appearance; at some points 3, 4, or 5 lobules are reunited in this way, being the remnants of a cured tubercle whose morbid product have been expectorated. At others, there are well defined masses varying from the size of a walnut to that of an apple, with walls of fibrous appearance and white yellowish, spongy, areolar, soft contents, divided by laminae starting from the wall and having a similar fibrous appearance. On other points there are real caseous masses with thick pus, resembling Roquefort cheese and having a thick fibrous wall with concentric layers, the thickness of which increases as one approaches the periphery.

Elsewhere there are tumors of dimensions varying from that of a walnut to that of a large apple; their section shows a tissue of fibrous appearance, traversed by bands of similar nature, but of a more grayish color, with here and there some projecting, yellowish granulations. Even here those lesions are surrounded by a very thick fibrous envelope with concentric layers of variable dimensions, layers much more numerous when the disease is nearer its disappearance. Finally the left anterior lobe, on the surface of which the lesions were late in the healing process, was completely collapsed; the pulmonary tissue was replaced by cicatricial tissue formed of thick and numerous lamellæ of fibrous appearance.

The liver was larger than normal and congested, containing tubercles of variable dimensions, surrounded by an inflammatory areola (a reactive inflammation intended to separate diseased tissues from healthy ones). Similar conditions were seen in the spleen: tubercles in process of healing.

Finally the lesions of the parotid gland were also significant of the progress towards recovery. The fistula was reduced to simple fibrous string; the tumor shown during the treatment in the anterior and lower part of the ear, was an encysted tuberculous abscess with evident signs of healing. This autopsy was instructive, showing much better than an autopsy of a cured animal the astonishing effects of this treatment.

Dr. H. Martin Roux (of the Bichat Hospital in Paris) made a microscopical examination of the lungs, glands, and liver of three different cows, treated with Cuguillère's serum, and found an evident process of healing by sclerosis and an abundance of phagocytes preceding the sclerosis. In all the organs tubercles of various size were encysted in thick fibrous envelopes. Roux was unable to detect, by Ziehl's method, a single Koch bacillus.

Similar experiments were reported on a number of tuberculous cows, after positive tuberculin injections, confirming the correctness of the diagnosis. The treatment by Cuguillère's serum was followed until the tuberculin test gave a negative reaction; and always the autopsy brought to light the same curative changes in more or less advanced degree of the healing process.

The cheesy matter found in healing or healed tubercles from animals treated with Cuguillère's serum was injected into rabbits and guinea pigs, not one of which contracted tuberculosis. Guinea pigs were then injected subcutaneously and into the peritoneal cavity with a dilution of human and bovine tuberculous pus. The three guinea pigs injected with bovine tuberculosis and three others inoculated with human tuberculosis reached after a while apparently the same stage of tuberculous cachexia and were submitted to the Cuguillère treatment. Three months later an autopsy showed that all the animals were cured and the cure was more decided in those inoculated with human tuberculosis.

Effects produced by the injection of the serum on bovine animals: Dr. Faure states that after 3 or 4 injections, the general condition is changed completely, and the changes are more notable when the animal is in a more advanced degree of tuberculosis. Without any grooming, the hair becomes smooth and bright, the skin more elastic, the appetite improved. There is a notable diminution in the volume of superficial glands proportionate to the number of injections; fluctuation, if it exists at the beginning of treatment, disappears; glands become hard and of fibrous consistence. The cough short, dry, painful, becomes stronger and more frequent and loose. Expectorations are more numerous and the products of excretion are so abundant that big, mucous, tracheal, sonorous râles may be heard at a distance. All those signs grow less and less in intensity and disappear completely the fifth or sixth day after the injection. With the increasing number of injections, all those effects disappear permanently after a time varying according to the intensity of the disease. Auscultation shows a decrease of initial symptoms, like gurgling, sibilant rales, pleuritic friction. At the end of the treatment, breathing is more hard, here and there absence of respiratory murmur; but never sibilant or mucous rales. This is explained by the complete absence of acute lesions, because, as the autopsy shows, near the lesion is healthy tissue without inflammatory zone of transition.*

It is well to remember that animal tuberculosis, as a rule, is not complicated by streptococcic (the chief ally of Koch's bacillus) or other infections. Hence, the uniform remedial action of the vegetable serum.

Let us pass now to human beings and cite a few cases of surgical tuberculosis, the first were furnished by Dr. Cuguillère himself in a paper read before the International Congress of Medicine held in Biarritz, April 19, 1903.

*Dr. Cuguillère and his colleagues, including the writer, will welcome the opportunity to repeat those experiments on animals under the supervision and control of any institution, society or body of physicians who will in the interest of science furnish subjects for experimentation.

1. Fungous osteoarthritis of the foot. Miss B. C., of Beziers. History of tuberculosis in the family. Tuberculosis of the tarsus from the age of six until the age of twenty-five. Four seasons at Balaruc (a thermal sodium chloride spring in the Herault, France) without effect. After twelve weekly injections, spontaneous elimination of tarsal necrosed bones. A season at the seaside activates this recovery maintained for the last four years. Foot composed of the calcaneum and metatarsal bones; complete mobility of the fibrous articulation.

2. Osteoperiostitis of the tibia. Miss L. L. Disease unyielding to seaside treatment. Recovery after six injections of serum. Later a season at the seaside.

3. Mr. L. Coxalgia. Impossible to produce ankylosis, unyielding to seaside treatment. After six injections patient walks with the help of a light cane. Followed by another course of thalassotherapy. Cuguillère never employs absolute immobilization; moderate exercise with massage and injections of his serum brings the complete resorption of fungosities.

4. Miss L. Y. Caries of the ribs. Recovery after five injections. Thalassotherapy after.

5. Mr. M. Osteoarthritis of the right knee; suppuration four years. Six seasons at Balaruc without effect. After twelve injections and one month's stay at Balaruc, recovery. Existing ankylosis previous to injections, partially relieved.

6. Tuberculous pleurisy. Miss B. C. Costal abscess open in pleura and externally. Pleural cavity containing 150 c.c. of fluid. Seaside treatment without effect. Resection proposed. Instead the serum was used to wash the cavity eight times. Fibrous adhesions formed. Recovery maintained after short season at the seaside and confirmed by radiography three months later.

It must be noted that the recoveries were due to the injection of the serum only. The seaside treatment was recommended as an additional tonic, and Dr. Cuguillère has done without it in later years. Cervical adenitis of a tuberculous nature was also cured by the serum, as well as tuberculous tumors of the breast, peritonitis, salpingitis, and lupus.

Dr. Cuvelier of Lens, Belgium, in a paper read before the International Congress of Tuberculosis held in Paris, October 2 to 7, 1905, presented the history of six cases of coxalgia, tuberculosis of the wrist, elbow, knee, treated with Cuguillère's serum. Some of them recovered, while the others were on the road to complete recovery at the time the paper was read. Since then, however, they all have recovered and Cuvelier says that Cuguillère's serum assures him a success in every case of surgical tuberculosis that he treats, voicing thus the unanimous experience of all those who have adopted this method of treatment.

What veterinary surgeon V. Faure has done in bovine pulmonary tuberculosis, Dr. Escoyez has undertaken to do in human pulmonary tuberculosis. His position in a Belgian sanatorium enabled him to employ various medications. He used phosote, similar to but less toxic than creosote, the open-air treatment, and Denys' tuberculin. Although he had good results with the latter, since 1904 he has used Cuguillère's serum because he has found that—(1) Its curative action is more rapid than that of Denys' tuberculin.

(2) It produces the degeneration of the microbes and phagocytosis the same as tuberculin. After a series of injections, varying according to the virulence of the bacillus and the gravity of the pulmonary lesion, all bacilli become granulated and are ingested by leucocytes.

(3) Cuguillère's serum acts in advanced cases where tuberculin is powerless. In extended lesions, tuberculin favors the generalization of congestion and hastens death because the organism is unable to react against the increased amount of toxin introduced by the tuberculin injection, or aggravated uselessly the preexisting symptoms.

(4) Cuguillère's serum increases considerably the appetite, facilitates digestion, and increases weight; with tuberculin there is a decrease in weight while the treatment lasts; an increase comes after its cessation.

(5) Treatment is easier by Cuguillère's serum. There are complicated rules in the employment of tuberculin, subject to the presence or absence of fever and its reaction or toxic effects; the employment of the vegetable serum (which is not toxic) is very simple, the minimum dose being 1 to 2 c.c. and the maximum 5 to 10, and very seldom 15 c.c. There is no reaction in apyretic patients; where fever is present there is a rapid and positive fall after 3 or 4 injections, and more rapid if the progress of the disease is more acute. Consequently, according to Dr. Escoyez, it will not be the temperature which will guide the physician in the determination of the dose, but the reaction produced in the lungs, the increase of cough and expectoration. But Dr. Cuguillère finds valuable indications also in the temperature. After the injection there is a reaction shown in the rise of the temperature the day when the injection of the serum is made or the day following. Cuguillère considers a sudden fall after the rise a good prognostic sign. Experience teaches him also that the dose must be increased when it fails to produce a rise in temperature any more.

(6) In desperate cases the vegetable serum alleviates the condition of the patients and lengthens their lives.

At the International Congress of Tuberculosis (Paris, 1905) and at the International Congress of Medicine (Lisbon, 1906), Dr. Escoyez reported the histories of forty cases of pulmonary tuberculosis treated with Cuguillère's serum. Since then he has treated 107 additional cases, making a total of 147. Seventy-one of these cases could not be considered because they died from other causes; 15 because they did not continue treatment, and 54 because, on account of their advanced condition, they received inoperative doses as an encouragement only. Of the remaining 76 at the time this summary was prepared 41 were radically cured; 14 were probably cured (general and local conditions excellent but rare bacilliferous expectoration due to the incomplete collapse of the affected portion of the lungs), 6 markedly improved, 3 improved, 3 were stationary or progressive, 8 died. The deaths were due to complications like peritonitis, grippe, and cardiac affections. With the radically cured the percentage was 53.8 per cent., and if we add the 14 practically cured, the 6 greatly improved, and the 3 improved, we have a total of 64 successful cases or a percentage of 84.2 per cent. Dr. Escoyez has classified his cases into six types: those who had (1) lesion of one apex; (2) lesions of the apex with more extended infiltration; (3) deep lesions involving at least one-half of the lung; (4) one lung involved in its entirety; (5) both apices, and (6) both lungs. The cases that died belonged to types 4 and 6.

Other Belgian physicians, Dr. Carcano of Milan, Italy, Dr. Cutiliero of Lisbon, Portugal, Dr. Rabaine, etc., have treated a large number of cases of pulmonary tuberculosis with good results.

The writer has had four cases of so-called local tuberculosis and four cases of pulmonary tuberculosis, short histories of which, though incomplete, are here presented. Two cases of cervical and submaxillary adenitis of two and three months' duration yielded to five injections each. Recovery, with general health improved. No relapse seven months after the completion of treatment.

Case I.—Mrs. B. L., Brooklyn. White swelling of the left knee-joint started 18 months before the patient was submitted to treatment by Cuguillère's serum. She had been treated previously. The joint trouble had been diagnosed and treated as rheumatism, and in June, 1907, she was operated upon by means of incision and curetting. Examination showed tuberculous granulations. At my first visit the circumference of the affected knee was 18 inches; that of the other knee 15. The patient had pains when she tried to walk; the knee-joint as well as the tibia very tender on slight pressure. Treatment was begun October 1, 1907, and continued until January 9, 1908, consisting of one injection of Cuguillère's serum of 4-5 c.c. every week. On January the circumference of the affected knee was 14½ inches; no tenderness on pressure. A vibrator was applied on purpose to test the tenderness of the tibia and knee-joint, and the patient asked for an increase of strength of the vibrator. She walked without a cane when last seen on February 27, 1908.

Case II.—Mrs. Q. Had a tumor the size of a walnut on the left breast which had been growing for twelve months. As she was under the charge of another physician no treatment was given. Five weeks later she returned to the office, saying that her physician had advised a radical operation of the breast. The tumor was now the size of a lemon and reached down to the areola of the nipple; it was painful and firmly adherent to the skin, but could be isolated so that it was plain that the mammary gland itself was not involved. My opinion was that the tumor was of tuberculous nature involving only the lymphatic glands. The fact of an abscess of the breast and suppurating axillary glands on the right side, operated on by incision some time previous to the actual induration in the left breast, confirmed my diagnosis. Eight injections reduced the tumor in size to 1½ inch vertically, and 1¼ inch transversally. The same measurements were found five weeks later, without further treatment. Patient seemed pleased to have avoided radical operation and in absence of local pain and visible tumefaction, discontinued treatment.

Case III.—My first two cases of pulmonary tuberculosis terminated in death. The first patient, when seen two months after the onset of the disease, had lost 21 pounds. His temperature was 104° F. Had daily chills, coughing and expectoration day and night, almost continuous perspiration (patient was obliged to change his flannel three or four times during the night); diarrhea; dulness over both lungs, more marked in upper lobes back and front, râles, bronchial breathing and bronchophony; numerous tubercle bacilli in the sputum. He had only six injections, which stopped the diarrhea and sweating, and quieted the coughing and expectoration; could sleep better, and the maximum temperature was 101° F. Owing to my absence from the city patient remained without treatment for seven weeks. On my return I found the patient in bed with hardly any appetite and all the symptoms greatly aggravated, with very weak heart, pulse 130 and more, and without resource for the necessities of life. No further serum injections were given; only palliative treatment until an additional acute congestion of the lungs brought his end.

Case IV.—The other case was one of an eighteen-

year-old girl, a patient of Dr. Thomas, with whose kind permission I began the injections. The patient was very low, just coming back from a sanatorium at Liberty, N. Y., and both physicians acknowledged that nothing could be expected from any kind of treatment. A pleurisy of tuberculous origin eight months previously had been followed with lung invasion. Weight 82 pounds. Very marked and striking retraction of the left lower posterior part of the thorax cavernous murmur with abundant râles at the apex and in the middle and lower lobe, two large caverns separated by a thin zone of doubtfully healthy lung tissue. The entire right lung was full of numerous rales of all descriptions, there was diarrhea (20 passages a day), appetite was lost, and there were perspiration, tachycardia, edema of lower limbs (no albumin in the urine), emaciation. Treatment prolonged life two months, relieving some of the symptoms, but the end came after precordial pains and repeated faintings.

Case V.—The two other cases are still under treatment but rapidly approaching complete recovery. The first one, a woman thirty years old, began treatment three months after the onset of her disease. Dullness at the apex and in the lower left lobe in the back, bronchial murmur and numerous moist râles, coughing and expectoration with occasional but very moderate temperature (101° F.), night sweats, loss of 25 pounds in weight, a few tubercle bacilli in the sputum. The woman was in the third month of her fourth pregnancy. After seven months of an uninterrupted treatment with 3 to 5 c.c. of Cuguillère's serum she regained the lost weight, her appetite became excellent, the general condition was good, and the local signs, except for very few dry râles in the lower part of the apex disappeared. She had a normal confinement, the baby weighed 7½ pounds at birth and now weighs 12 pounds; it is nursed by its mother. During the treatment the patient was doing all the housework, cooking, washing, ironing, and sweeping. As an additional treatment for a short time she had a few injections of Deutschmann's serum, which reduced the number of streptococci found in the sputum. At the last bacteriological examination no tubercle bacilli were present, according to the Board of Health; Dr. Jeffries of the Polyclinic was likewise unable to find them.

Case VI.—The last case is that of Miss S., who was taken ill in the latter part of January with what her physician thought was the grip. When she left the bed she was still weak and cough and expectoration continued with practically no rise in evening temperature. There was dulness under the left clavicle, at the apex, and in the back and below the crest of the scapula, with hard breathing mucuous râles; she had intense pain on the left side of the thorax, and in the knees and feet. The tubercle bacilli were reported at two examinations to be few and moderate in number respectively. Treatment began nine weeks ago. Only a few occasional dry râles can now be heard with slightly reduced dulness. The patient coughs very little and expectorates so little that she was an entire week collecting a sufficient amount of sputum for a bacteriological examination; tubercle bacilli, however, still present. General condition is excellent. Intratracheal injections with Cuguillère's serum were attempted in this case, but owing to a great sensitiveness of the patient's throat they could not be made. At every séance small amounts of the serum were repeatedly placed at the base of the tongue, and by sudden deep breathing the patient was made to draw it through the trachea. This had an evident action on the tickling cough and perhaps on the character of the expectoration. The liquid has apparent antiseptic and healing properties when applied to superficial ulcerations. Hence this trial, which I intend to follow up in future cases.

Are we entitled to draw any favorable conclusions from this presentation of the treatment of tuberculosis by Cuguillère's serum? Does it have any real therapeutic value? The answer is not difficult. How is it that with other methods of treatment so many drugs have been advocated? Because the treatment of the majority of practitioners is symptomatic only. Cuguillère's serum attacks the disease itself and its direct cause, Koch's bacillus, which it destroys. It helps recovery by promoting the fibrous transformation of the tubercle in whatever organ or organs it exists. It needs no additional drugs to suppress and prevent hemoptysis, to reduce temperature, to stop diarrhea and night sweats, to arouse the appetite, to strengthen the heart's action, to increase the weight, to stop cough, expectoration, and pain, to facilitate the resorption of pleural, peritoneal, or articular effusions.

To be sure, many persons with pulmonary tuberculosis have been cured and are being cured with other drugs and sun and air, and some have been cured without the help of any treatment, but with Cuguillère's serum the recovery is almost mathematically certain, provided the organism has sufficient vitality and recuperative powers and has not fallen into decay. The difference between Professor Dettweiller's 14 per cent. radically cured cases by sanatorium treatment and Dr. Escoyer's 53.8 per cent radically cured by Cuiguillère's serum, is eloquent in favor of the serum, especially when we take into consideration the absence in Escoyer's patients of all the comforts afforded to sanatorium patients. But the unanimous testimony of all physicians and surgeons who have employed the serum on new or far advanced cases of *surgical* tuberculosis that they had 100 per cent. recoveries, places on Cuguillère's serum the highest therapeutic value, not possessed by any single remedial agent, not even excepting diphtheria antitoxin.

It may be admitted without difficulty that a large number of cases of pulmonary tuberculosis, which have gone beyond human help, will meet the inevitable. But at the same time, it can be said that consumption will be a thing of the past if, with the absolute certainty of permanent recovery in all cases of surgical tuberculosis (without immobilization in bed, Paris plaster, or other appliances—except where the vertebrae are involved), every case of established or suspected pulmonary tuberculosis and every case of so-called "bronchial cold" lasting over a month or two is submitted to the treatment by Cuguillère's vegetable serum. In case of a recurrence of the infection, a few more injections will control the disease.

Many readers of this article will undoubtedly question the accuracy of its statements; but let them repeat the experiments on animals, in one or more cities, under the most exacting conditions that they may name; then let them use the treatment, on skin, glands, bone, joint, prostatic, and testicular tuberculosis, so that they can see with their own eyes and feel with their own fingers; let them treat ovarian tuberculosis of which so little is heard as to their nature, and of which so many go under the surgeon's knife; and they will have abundant personal information that will enable them, with positive convictions, to begin treating laryngeal and pulmonary tuberculosis.

104 W. Forty-ninth Street.

MALNUTRITION AND SOCIETY.*

By INEZ C. PHILBRICK, A.M., M.D.,
LINCOLN, NEB.

Recent comprehensive works on dietetics, scientific in character; valuable experimental work under way; an increasing number of articles upon the subject in current medical literature; prominence given the food factor in the treatment of certain diseases, notably gastric and intestinal disorders and tuberculosis; professional discussion of the researches of Chittenden, and of certain dietetic fads —as Fletcherism—emphasizing some one phase of the nutritive process, indicate increasing professional interest in the food factor in the prevention and cure of disease. That, however, this interest is, as yet, wholly inadequate is conceded. Voicing this inadequacy of interest, W. Gilman Thompson, in his "Practical Dietetics," quotes approvingly the assertion of Bennett in 1858, that "of all the means of cure at our disposal, attention to the quantity and quality of the ingesta is by far the most powerful"—a statement which, in the light of recent noteworthy sociological investigations, is hardly open to the charge of being a stimulative, if too enthusiastic statement of the possibilities of regeneration through food. It is not surprising that, professional interest in nutrition concretely considered being inadequate, consideration of it in its vast social relations, from the sociological rather than the medical standpoint, has been neglected. This is the more unfortunate as it is to the medical profession that the social worker must go for data justifying remedial measures and holding forth promise therein.

In the medicosocial, rather than the strictly medical, discussion of malnutrition we are more concerned with its chronic manifestations consequent upon deprivation of food in quantity, from necessity, or in quality, from vicious choice, than with inability to assimilate food provided or excess of food, although the exhaustive treatment of the subject demands recognition of the importance of these phases. Of the excess of food a lay authority on dietetics says: "It is the belief of most students of economics and sociology"—and, I may add, of medicine—"that it is the overfed among the nine-tenths not submerged, who are being eliminated by the various diseases of modern life—apoplexy, heart disease, Bright's disease, etc.—and that the sterility of the better-placed portion of the community is largely due to the plethora of food and drink."

No one period of life possesses a monopoly of interest in malnutrition; but in its relation to childhood, the years when formative processes are under way, lies its chief importance. Centuries ago, Hippocrates said truly: "Old men bear want of food best; then those that are adults; youths bear it least, most especially children; and of them the most lively are the least capable of enduring it."

For twenty-five years, and more, in several European countries, and recently in our own, malnutrition as a social problem, a part of that of poverty in general, has at various times and in differing phase come up for discussion and solution, interest having been directed thereto through exhibition of physical inefficiency in candidates for army and navy, in industrial workers and among children in the public schools. Investigation and advocacy of remedial measures have, therefore, been instituted by predatory as well as humanitarian interests. To-day the vast extent of the problem is conceded. Discussion centers about measures of relief.

In Great Britain, the only country for which I have been able to obtain the history of a movement toward the discovery of the extent to which malnutrition exists and its remedy, two lines of investigation have been followed—the charitable-social and the scientific-social. Under the former head are to be classed the several investigations of the London Charity Organization Society and the London School Board, and under the latter head those of certain medical men, notably Crichton-Brown, Paton, and Dunlop, and of four investigatory bodies of national scope, chief among them "The Interdepartmental Committee on Physical Deterioration," 1904.

That to-day in the United States there exists a vast and rapidly growing problem of malnutrition is inconsistent with our youth, our resources, and our political institutions, but is none the less indisputable. The most convincing books by American authors covering this field of investigation are "Poverty," by Robert Hunter, and "The Bitter Cry of the Children," by John Spargo. To one unfamiliar with conditions obtaining among the poor of our large cities their terrible arraignment of modern social conditions comes as a challenge to denial of the validity of their conclusions. But the preponderance of authoritative opinion in the discussions which these books have elicited in recent periodicals approves them as fair and trustworthy.

Investigation of the problem of malnutrition is most difficult. It eventuates largely in the weighing of personal opinion. Statistics, as at present tabulated, do not differentiate malnutrition from other evils incident upon poverty—inadequate clothing, insanitary homes, parental neglect; nor can the effects of overfeeding among the luxurious class be considered apart from their various dissipations, sloth—mental and physical—and hothouse environment.

Dr. Alfred Eichholz, an important witness before the Interdepartmental Committee on Physical Deterioration, who for six years had devoted himself to the investigation of the problem, estimated the number of the children in the London elementary schools who were actually underfed as 16 per cent., it increasing to 33 per cent. in certain poverty-stricken districts. Dr. Macnamara, member of Parliament, another witness, for thirty years associated with the London schools as teacher and member of the school board, estimated that 20 per cent. of the working-class children are habitually underfed. The *Spectator* in comment declares: "We do not in the least question the statement of Dr. Macnamara, that 20 per cent. of the children of the working classes are suffering from malnutrition."

Of conditions in the United States, Hunter says in "Poverty": "There must be thousands, very likely sixty or seventy thousand, in New York City alone, who often arrive at school hungry and unfitted to do the work required"; an assertion which he reiterates and fortifies in the *Reader* as, "the day-by-day and week-by-week undernourishment of seventy thousand children." Spargo, in an investigation in sixteen New York schools in which he could get the cooperation of principals and teachers, found 23 per cent. underfed. Correlating his results to those of Lechstrecker in New York, and of certain investigators in Philadelphia, Buffalo, and Chicago, a total of 40,746 children is obtained, of which number 34.65 per cent. either went breakfastless to school habitually or got miserably poor

*Delivered before the Nebraska State Medical Association, May 21, 1908.

breakfasts of bread alone or bread with tea or coffee. The breakfast test has been found the most practicable one by teachers and social workers, the breakfast of the child of poverty typifying his every meal. Let me instance a table given by Spargo of the meals for one day in a "typical family" in a district of Irish unskilled laborers in New York City:

Family	No. Children in School	Breakfast	Lunch	Supper
No. 1	2	Bread and tea...	None.....	Bread and tea.
" 2	1	None.....	Soup from charity.....	Bread and coffee.
" 3	1	Coffee and dry rolls.....	Bread and coffee.	Bread and tea.
" 4	3	Bread and tea...	None.....	Bread and tea.
" 5	2	None.....	Soup with soup meat.....	Piece of bread.
" 6	1	Bread, coffee and jam.....	None.....	Bread tea and jam.

Food was and is the prime necessity of mankind, and effort to obtain it supplied the chief impetus in early human development. Natural food supply determined social aggregation and the character of prevailing customs and laws in primitive society. Latest scientific authority demonstrates "a connection between an abundance of nutrition and females and scarcity and males in relatively higher animal forms and in man"; that, in other words, "nutrition is one of the most important factors in determining sex." Natural selection, operating through food abundance or food scarcity, determined in large part birth and death rates among primitive peoples.

Vital statistics show that more children are born among the poor than among the rich, which fact would apparently negative the direct influence of sufficiency of food upon fecundity. In the endeavor to reach a fair estimate of this influence, the relative significance of many facts must be weighed. The larger birth rate among the poor doubtless depends, in part, on their having been not weaned away from primal healthy interest in home and children through luxurious living and the cultivation of selfish interests; upon lesser desire to avoid the responsibility of a family, or the lack of blood-money to procure an abortion, or a greater dread of consequent illness which they can ill afford. Possibly more often unlettered and, it may be, unthinking than the well-to-do, they recognize less clearly the social responsibility incurred in numerous progeny. An increasing birth rate in times of plenty indicates, certainly, not alone the influence of more abundant food supply, but also increased assumption of marriage and lessened temptation to criminal abortion. A decreased birth rate among luxurious livers is inconclusive as regards the relation of excess of food to sterility, other factors, as mental and physical sloth, entering in.

Correlated to the question of the influence of nutrition upon fecundity is that of the influence of the nutrition of the mother upon the fetus *in utero*, discussion hereupon constituting a chapter of intensest interest in the deliberations of various investigatory bodies in recent years. The theory of the postnatal origin of physical degeneracy and mental and moral as well, as opposed to that of its antenatal origin, has nowhere been so authoritatively and convincingly expressed as by distinguished scientific and medical witnesses before the Interdepartmental Committee on Physical Deterioration. This theory, briefly stated, is as follows:

"Nature gives every generation a fresh start." She lays no handicap upon the unborn child, inheritable disease being excluded. Among the very poorest classes the number of children born strong and healthy is as great as among the well-to-do. It rests with society to secure such postnatal environment for the child as shall develop physical efficiency in all alike—a theory, if true, of vast social significance.

The chief medical witnesses championing this theory were Prof. D. J. Cunningham, professor of anatomy in the University of Edinburgh and president of the Anthropometric Committee of the British Association, who maintained the existence of a mean physical standard which is the inheritance of the people as a whole, and the non-transmissibility of acquired characteristics the result of poverty; Dr. Eichholz, who testified, "The number of children born healthy, even in the worst districts . . . would seem not to be less than 90 per cent. I have sought confirmation with medical colleagues in public work . . . and have always been strengthened in this view. . . . In fact, it almost appears as though the unborn child fights strenuously for its own health at the expense of the mother, and arrives in the world with a full chance of living a normal physical existence;" and Dr. Edward Malins, professor of obstetrics in the University of Birmingham and president of the London Obstetrical Society, who maintained that the testimony of experienced persons was on the whole in accordance with the views expressed by Dr. Eichholz, and that 80 to 85 per cent. of children were born physically healthy, whatever the condition of the mother might be antecedently. The report of the Interdepartmental Committee says: "The chief physician to the Royal Maternity Charity issued a circular to medical gentlemen who assist him in different slum quarters, and he put to them this question: 'What number per cent. of newborn children among the poorest classes would be capable of living a normal physical existence were it not for neglect, poverty, and ignorance?' . . . He got answers giving a percentage for the total of 86 per cent."

In refutation of this theory the researches of Dr. Noel Paton, of Edinburgh, are referred to frequently in the deliberations of the committee, and are cited in Spargo's work. Paton, in the *Lancet* for July 4, 1903, reports the results of the regulated feeding of fourteen pregnant guinea pigs, seven being abundantly fed and seven underfed. The average weight of the litters of the well-fed was 28 per cent. above that of the litters of the underfed, the least difference between individuals being 10 per cent. Paton quotes Prochownick's results of the regulated feeding of forty-eight pregnant women with contracted pelves, with the aim of making labor easy by reduction of the size of the child. In 28 male children the weight at birth was 11 per cent. below the average; in 24 females, 14 per cent. below the average. Paton concludes as follows: "These observations, though few in number, are so concordant that they warrant the conclusion that the size of the offspring depends very directly upon the diet and nutrition of the mother during pregnancy. . . . To the physiologist the point of chief interest seems to be the demonstration of the extent to which the tissues of the mother can be utilized for the construction of the embryo. The nourishment of the maternal tissues seems to take precedence over the nutrition of the fetus."

These conclusions seem to me hardly to be warranted, they resting upon too few data. Besides, weight and nutrition are by no means synonymous,

there being a considerable latitude in weight consistent with good nutrition. To get the opinion of our foremost obstetricians and pediatrists upon this point, I addressed letters of inquiry to the professors of obstetrics in the following medical schools: Harvard, Johns Hopkins, University of Pennsylvania, Columbia, Cornell, Northwestern University, Chicago University, University of Michigan, Jefferson, and to the professors of pedriatrics in Harvard and Columbia Universities. The replies, briefly summed up, are as follows: Of the obstetricians three maintaned the causal relation of malnutrition in the pregnant woman to antenatal degeneration in the fetus; four denied this relation; one agreed "in general" with the postnatal origin of degeneracy; and one was unwilling to express an opinion for lack of sufficient data. Of the pedriatists, one attributes much less weight than he did formerly to the influence of antenatal conditions, and the other was unwilling to express an opinion without further data. Thus opinion among these authorities is slightly in favor of the postnatal theory of the causation of degeneracy.

In a recent comprehensive and valuable study of "The Effects of Urban Congestion on Italian Women and Children in New York City," by Dr. Antonio Stella, printed in the MEDICAL RECORD of May 2, 1908, the author says: "Almost all Italian infants are born strong and healthy, and their weight is often above the average, even when their mothers look pale and sickly and live in the poorest districts." Among our immigrants it is well known that the Italians are the most notoriously ill-nourished, they endeavoring to maintain themselves here on the same poor diet which sufficed in Italy. "Nothing," says Hunter, "could show the misery resulting from unemployment and underfeeding more clearly than the physical condition of the Italians in this country."

The direct and powerful influence of poverty upon the death rate is established, but to give to each factor in poverty its due proportion of responsibility is, with our present data, impossible. The fact that infantile mortality has not decreased with general mortality following upon the vast sanitary reforms of recent years indicates the preponderant importance of the food factor, as does also the decreased infantile mortality in localities here and abroad where pure milk depots have been established. It is obviously impossible to determine the relative importance of malnutrition in the child, with consequent increased vulnerability, and bacterial contamination of the milk supply. All authorities testify to the marked lack of resistance to disease of the poorly nourished child. Feeble powers of digestion and assimilation consequent upon malnutrition impose defeat of its cure—a hopelessly vicious circle. As diseases in which the nutrition factor is most active in causation, Spargo cites measles, inanition, convulsions, phthisis, bronchitis, pneumonia, croup, debility and atrophy, and diarrheal diseases—a classification which is medically sound. Of the 151,732 deaths among infants and children from the above diseases during one year in the United States, Spargo attributes 51.57 per cent. to poverty and, more specifically, to malnutrition. Statistics are not available giving the percentage of frequency of rachitis. Dr. Stella says that 75 to 80 per cent. of Italian children in New York City develop rachitis, and of these 65 per cent. are breast-fed. Admittedly, by all authorities, rachitis is a large factor in morbidity and mortality from other diseases. Of the rachitic child Osler says: "The condition of the child is such that it is readily carried off by intercurrent affections, particularly those of the respiratory tract." Ashby puts rachitis first in the causation of infantile convulsions, in which he has the support of pediatrists generally. The mortality from measles is affirmed by Ashby, Rührah, and many other authorities, as practically nil among the well-nourished children of the well-to-do classes. Dr. S. A. Knopf puts underfeeding first and bad housing and insanitary conditions second as factors in the causation of tuberculosis. Lawrason Brown, in Osler's "Modern Medicine," puts food first in the prevention and treatment of tuberculosis. And I might go on indefinitely, digging out inadvertent references in textbooks on clinical medicine to sustain the thesis that deprivation of food in quantity or quality, or both, is the most important aspect of poverty in its relation to morbidity and mortality from disease.

Dr. Ralph D. Vincent, physician to the Infants' Hospital at Hampstead, organized in 1903 to "grapple with the problem of the infant," testified before the Interdepartmental Committee on Physical Deterioration: "It is food, and food alone, that is responsible. Sanitary conditions do not make any real difference at all." Of admissions to the New York Babies' Hospital in one year, in 75 per cent. of cases malnutrition was found to be the most prominent feature (Quoted by Spargo). The replies of the superintendents of six large dispensaries, in which 25,000 children are treated annually, when asked what proportion of the cases treated, conservatively estimated, were primarily due to inadequate nutrition, yielded an average of 45 per cent. (Quoted by Spargo).

The direct causal relation of poverty to physical degeneracy, "the physical superiority of the well-to-do over their less fortunate fellows," is established beyond question. As to the relative importance of the food factor in inducing physical degeneracy, the report of the Interdepartmental Committee on Physical Deterioration says: "Among the factors that make for juvenile degeneracy, with the single exception of Mr. Edward Rees . . . all the witnesses concurred in claiming the first place for food. 'Food,' says Dr. Eichholz, 'is the point about which turns the whole problem of degeneracy.'" The results of the feeding of school children in the largest cities of Europe, and to a slight extent in New York City; comparison of the children in pauper, reformatory, and industrial schools, where they are fed as well as instructed, with children in the elementary schools; feeding experiments in certain schools for defectives and certain summer camps for city children—all prove the direct relation of proper feeding to the development of the physical and mental capacity.

Of recent arraignments of the public school systems of England and the United States as inadequate to accomplish their aim, let me quote: "The State, whose sacred duty it is to protect the poor and helpless, has been robbing the children of the poor and leaving them to perish for lack of that maintenance to which they are entitled. . . . This injustice brings its own punishment, for our national system of education is spoiled, and the children grow up feeble and diseased to fill our hospitals, workhouses, and gaols" (Sir John Gorst). "It is grotesque to lavish money on education for those who are unfit physically and mentally to receive the education offered them" (Dr. Macnamara). "Education, whether physical or mental, is seriously retarded, if not practically impossible, where the body is improperly or imperfectly nourished. What a farce it is to talk of the schools pro-

viding equal opportunities for all, when there are hundreds of thousands of children in our city schools who cannot learn because they are hungry!" (W. H. Maxwell, Superintendent New York Public Schools). "Hunger," said Livingston, the great explorer, out of his experience among primitive tribes, "has a powerful effect upon the temper." "Courage, cheerfulness, and a desire to work depend mostly on good nutrition," said Moleschott. And I might quote more to the same purport.

Physicians are all familiar with that condition of irritable weakness due to starvation in convalescents from acute disease, and with the morbid fears and fancies and undependable intellectual and moral judgments of undernourished chronics. The child the victim of underfeeding is in like case. I quote: "Not graves alone, but hospitals and prisons are filled with the victims of childhood poverty. They who survive go to school, but are weak and nervous, dull, and backward in their studies. Discouraged, they become morose and defiant, and soon find their way into the reformatories for truancy and other juvenile delinquency. Later, they fill the prisons, for the ranks of the vagrant and criminal are recruited from the truant and juvenile offender. Or if, happily, they do not become vicious, they fall in the struggle for existence . . . and sink into the abysmal depths of pauperism."

Conceding that, outside inheritable disease, degeneracy, physical, mental, and moral, is largely the result of postnatal environment, it behooves society to remove or to reform those environmental conditions which are responsible therefor. Chief among them is the modern industrial system. Spargo, in "The Bitter Cry of the Children," cites a cartoon which appeared in an anarchist paper, *La Revolte*, "showing a woman, haggard and fierce of visage, seated upon a heap of child skulls and bones, in her gnarled and knotted hands holding the writhing form of a helpless babe, whose flesh she is gnawing with her teeth, with underneath, in red ink in rude characters, these words: 'The Wretch! She Devours Her Own Children!'"—an entirely just characterization, not alone of France, but as well of every civilized nation, acting through the modern industrial system. In our gross inconsistency we do not allow natural selection, operating through the barbarities of modern industrialism, to eliminate its victims. We maim the children, handicap them, force them into the ranks of the incompetent and delinquent, and then feed them on balanced dietaries in reformatories and penitentiaries.

Next in importance to reform of the industrial system is reform of the family. As at present constituted, the modern family is an anomaly. It alone among our social institutions is founded upon ignorance and incapacity. Outside the ranks of unskilled labor, for no other calling in life is preparation and training deemed unnecessary save for that of home-keeper. It is an anachronism that the feeding of the people should be in the hands of ignorant amateurs. What wonder that a large portion of modern households "spend their money for that which is not bread and their labor for that which satisfieth not!" Is it any wonder that the small remnant of children born into homes where cabbage is fed to a three-days-old infant, beer and bacon to one barely six weeks old, and sausage, bread, and pickles to a mature infant of seven weeks, should later, as school children, spend their luncheon pennies for pickles, adulterated candy, cream puffs, stale ice cream and decayed fruit—found by social workers and teachers to be the favorite dietary among the children of the poor?

Under the present constitution of the family, not until the State requires of candidates for marriage certificates of health, character, proficiency in housekeeping, and mature age, will conditions in the household markedly improve. The teacher of domestic science in the public schools will serve a useful purpose in the years of transition to the inevitable placing of the feeding of the people in the hands of experts. The highest function of the home is not that of the restaurant, and to deprive it of this function will neither pervert nor subvert it.

Among other measures that will aid in the cure of poverty, with its attendant evils of malnutrition and degeneracy, are the enfranchisement of women, bringing into the service of the State that class whose experience and training throughout centuries best fits them for the administrative side of government, in other words, social housekeeping; proper distribution of immigration; the establishment of pure milk depots under voluntary or municipal support, as are found in twenty cities of the United States (sixteen under philanthropic support and four under municipal), and in many of the cities abroad, the milk free or at such price as the financial ability of the customer can afford; the establishment of model restaurants, as has been done by the Baron de Rothschild in Paris, where food of the best quality is provided at moderate prices for the working classes; the feeding of school children under certain conditions; the assumption by the medical profession of its specific responsibility in the way of school inspection and in providing the necessary data out of its experience, for correct judgment and wise remedy in legislation, said legislation to carry with it provision for its enforcement—often a fatal lack.

That the chief items in this program of reform are socialistic in their nature is inevitable, their function being to offset those evils which have sprung out of the intensely individualistic attitude of modern society—every man for himself, every family by itself. The public school—a socialistic institution—does, in some measure, offset the pernicious influence upon the children of individualistic family tradition and practice, and is a potent factor in social reform. Outside acrimonious discussion and political warfare over the reform of the modern industrial system, no item in this program has given rise to more comment than the feeding of school children, which is carried on by voluntary or municipal agency in certain large cities of Great Britain, Italy, France, Austria-Hungary, Belgium, Denmark, Switzerland, Norway, and, to a slight extent, in the United States. Discussion as to the wisdom of this measure waxes warm between the advanced social workers on the one side and the socialistically inclined on the other. Obviously, the supply of social workers qualified to undertake the individual treatment of every child the victim of malnutrition, as is demanded by the former class, is utterly inadequate. Belonging to neither of these two classes are those in municipal or State authority who, in the interest of a false economy, would spare the rates at the expense of the child. The struggle with the dissolute and vicious parent is a long and wellnigh hopeless one. We cannot split hairs as to means and ways while the children are being "starved into death or stunted into physical and moral deformity." If we cannot regenerate the parent of this generation, we can predetermine the character of the parent of the next, in the words of a Norwegian councilman, by "saving the children from the hostile forces of un-

equal economic conditions, and securing them equal opportunity and helpful conditions for the development of their highest and best gifts." "That there should one man die ignorant who had capacity for knowledge, that I call a tragedy," said Carlyle. To prevent such we may well relax somewhat in the interest of expediency the rigor of rules for social regeneration which, in spirit ideal, in practice are inadequate.

In closing, let me quote Spargo's hopeful outlook toward the future: "I look to see in the near future some effort made to establish a standard of physical well-being for the children. I expect to see the community insisting that some provision shall be made whereby every child born into the world will receive sufficient food to enable him to possess enough vitality to overcome unnecessary and preventable disease, and to grow into a manhood physically capable of satisfactorily competing in industrial and intellectual pursuits."

VAGINOURETEROSTOMY AFTER NEPHRECTOMY FOR PYONEPHROSIS DUE TO A "SIGMATE" CONSTRICTION OF THE URETER.*

BY A. ERNEST GALLANT, M.D.,
NEW YORK.

HAVING removed the kidney what disposition shall we make of the ureter? In endeavoring to answer this question in a way which will best conserve the interests of the patient, immediate and remote, several plans deserve consideration.

First, and oldest of them all, the ureter may be drawn up as far as possible, cut off short, ligated, and dropped back into its retroperitoneal pocket, sometimes to remain quiescent, in some instances to distend with pus or urine, and discharge through a lumbar fistula setting up inflammatory adhesions which greatly add to the difficulty of its subsequent removal. Of late years, except in few instances, this plan has been relegated to the land of "has been."

The second method, that of bringing the ureteral stump out through the lower angle of the lumbar incision and fastening it to the skin, has proven of great value in many hands, as it affords free vent to any pus which may accumulate in the ureter, and for the introduction of drugs which will heal or destroy the mucous lining of the ureter and facilitate atrophy of that tube. Schede treated 22 cases by this plan after extirpation of tuberculous kidneys, and of the 16 patients who recovered not one was troubled with a permanent fistula.

Ureterectomy.—According to Bovée, the first partial ureterectomy was done by Tuffier, in 1891, and the first complete removal, by Poncet, in 1895. The "American" operation, nephroureterectomy at one sitting, was first carried out by Kelly in December, 1895.

Since that time many operators have removed the ureter *in toto*, primarily or secondarily, chiefly where the ureter has been the seat of tuberculous

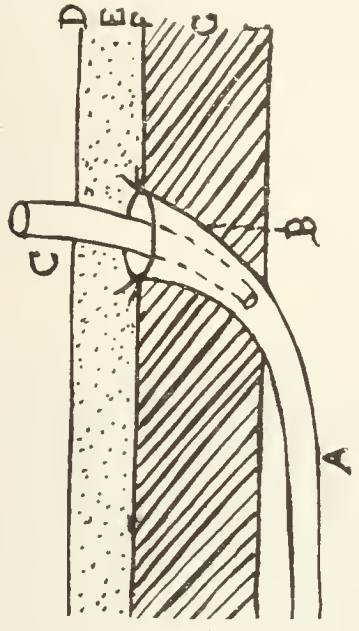

FIG. 1.—A, ureter; B, stump of renal pelvis sutured to lumbar fascia; C, drainage-tube; D, skin; E, subcutaneous fat; F, lumbar fascia; G, lumbar muscles.

disease, and in order to prevent or overcome tuberculous infection of the bladder or the danger of infecting the opposite kidney. Of the 17 cases collected by Bovée (*American Medicine*, June 6, 1903) only two ended fatally.

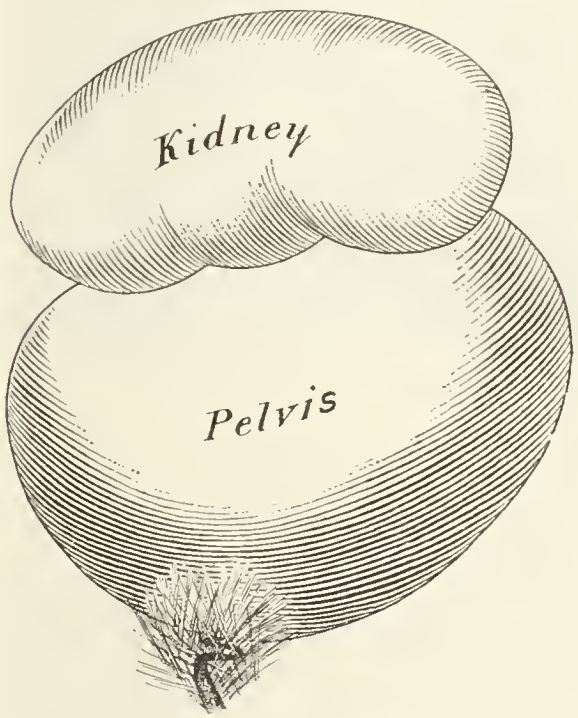

FIG. 2.—Hydronephrosis due to an S-shaped bend in the ureter, bound down by fibrous bands.

In view of the fact, admitted by all operators, that primary removal of the ureter adds to the length of time and difficulty of the operation and the likelihood of shock, and that in secondary operation, when called for in the presence of symptoms of retention in the ureter, the added inflammatory

*Presented to the Section on Surgery of the New York Academy of Medicine, January 3, 1908.

adhesions cause greater difficulty of removal and liability to infection, I have carried into effect the following plans after the removal of a pus kidney due to stricuture of the ureter, subsequent to hysterectomy. In order to secure ample drainage of the ureter should trouble arise, the lower inch of the kidney pelvis was cut away with the ureter and sutured to the lumbar fascia, thus leaving a funnel-like opening in the subcutaneous tissue, into which a drainage tube could be easily introduced (Fig. 1). Suppuration did take place, the skin was incised, and drainage was easily established. This was repeated three times, and only after the third black silk knot used to ligate the renal vessels was discharged did the wound heal. The patient has not been troubled since December, 1904. Evidently the ureter, though occluded about four inches from the bladder, gave no trouble.

At the time when this plan was reported (*American Medicine*, 1903, xi, 65-67) I suggested the practicability of vaginal implantation of the ureter: "After nephrectomy for tuberculous kidney, pyonephrosis without ureteral obstruction, it might be well to afford additional drainage and divert the ureteral secretion from the bladder by resection of the vesical end (after introducing a catheter into the ureter), exposing the ureter, through the vaginal wall, cutting across, closing the vesical stump, and suturing the proximal end into the vaginal wound, that the ureter may drain directly into the vagina, where it can do no harm."

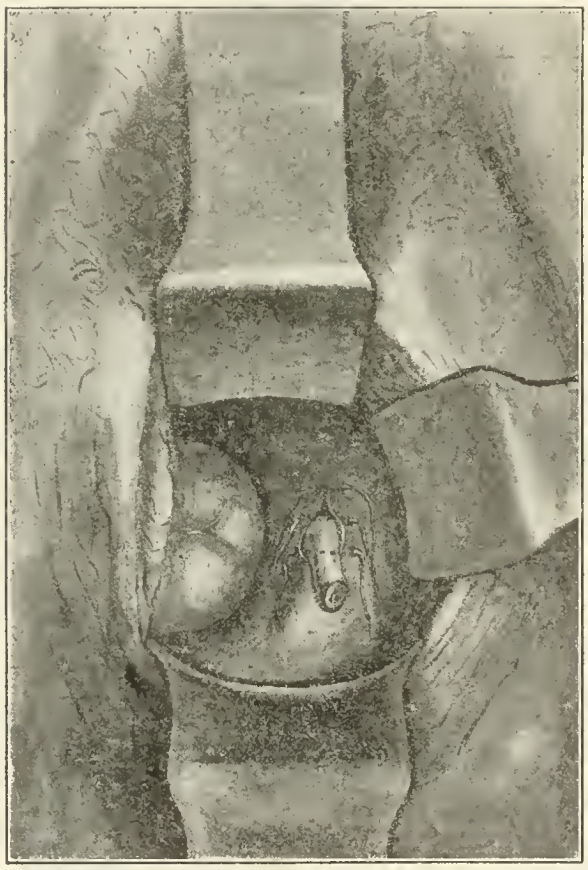

Fig. 3.—Vaginoureterostomy; resected ureter brought into vagina; untied sutures in place; upper suture surrounds ligated vesical end of uterer.

The following case afforded the opportunity to put this method into practice.

On December 29, 1905, at the request of Dr. L. Howard Moss, I first saw the patient here presented, who was then troubled by a cystic tumor lying on the left side of the abdominal cavity, its center opposite the umbilicus, movable up and down two or three inches; from the history it seemed to have arisen from the pelvic cavity. Through an anterior exploratory incision it was found to lie behind the peritoneum and to be made up of the dilated kidney and pelvis. I operated on January 17, 1906, at the Jamaica Hospital. Through a lumbar incision the pelvis was opened and emptied of more than 1,000 c.c. of urine, but no opening to the ureter could be found. On exposing the ureteropelvic junction the obstruction was found to be due to an S-shaped bending of the ureter which was bound down by dense adhesions bands (Fig. 2) completely precluding the outflow of the urine. As soon as these bands were freed from the adhesions, a probe was easily passed down to the pelvic brim. Owing to the large size and thinness of the kidney no attempt was made to suture it, but it was supported by gauze packing, and urine flowed freely into the bladder for several days until the packing was removed. Later the kidney seemed to drop and the obstruction recurred so that on April 25, 1906, the kidney was removed, leaving part of the pelvis and the ureter *in situ*. From that time there was some discharge from the lumbar sinus of pus mixed with urine.

On September 18, 1907, at the Baptist Deaconess Home, vaginal implantation of the ureter was carried out. A catheter was introduced into the ureter and passed easily to the cavity in the loin. With this as a guide, stiffened by a metal probe, an incision was made through the left vaginal vault exposing the ureter. While endeavoring to draw down the ureter with mouse-tooth forceps the bladder was torn into and through this opening the index finger was used to hook down the ureter, rendering resection quite easy. The ureter was cut off about one inch from its bladder attachment, the proximal end was brought down into the vagina and sutured there. Two catgut sutures were inserted through the vaginal wall including the bladder end of the ureter, closing it off permanently. The discharge from the lumbar sinus at once lost its urinous character and changed to thick pus. September 30, the vesicovaginal fistula was closed by silkworm suture and remained closed. The lumbar sinus has also closed. A small papilla in the vagina now marks the site of the ureteral implantation.

In conclusion: The extreme gravity of the operation and high mortality following nephrectomy, without coincident removal of the ureter, lead us to devise simpler methods than ureterectomy, and by implantation of the "pelvic funnel" into the lower angle of the lumbar wound, subcutaneously, we (*a*) shorten the time of operation; (*b*) reduce the likelihood of shock; (*c*) frequently secure primary union; or (*d*) drain in a simple, safe, and curative way.

Should the urine regurgitate from the bladder, or in case of tuberculous infection of the ureter, we resect the latter, close to the vesical end, and suture the proximal end into the vaginal vault.

When there is stricture of the ureter the combination of lumbar and vaginal implantation gives free vent at both extremities.

In tuberculous infection of the kidney and ureter it might be well to form a vaginoureteral fistula as a preliminary to nephrectomy in order to shunt the infected stream from the bladder, and to learn more particularly of the capacity of the other kidney.

The results of Schede's plan demonstrate that with proper drainage even tuberculous ureters heal and atrophy; therefore we need not hesitate, in men, to implant the ureter into the rectum.

CARING FOR THE MOTHERS OF INFANTS.

THE upbringing of young children is a matter which has been arousing an extraordinary amount of interest in all civilized countries during the past few years. Perhaps this has been particularly the case in France and in Great Britain, for in both of these lands the birth rate is rapidly and progressively decreasing, while infant mortality is excessively high. Indeed, so far as France is concerned, the birth rate is at so low an ebb that population year by year is gradually becoming less and less, and in the large cities infantile mortality is high. In Great Britain the birth rate as yet considerably exceeds the death rate, but the proportion is continually undergoing considerable alterations and the population does not increase at the rate which was formerly the case. In America the birthrate among native born Americans shows a steady decrease, infantile mortality is high in most of the cities, and if it were not for the fecundity of immigrants and of those of alien stock, and for abundant immigration, this country would soon have to lament a falling off in the population, as indeed it has temporarily at present, owing to the large emigration and decreased immigration during the past year. In France and in Great Britain vigorous efforts are being put forth to check infant mortality. France was the pioneer in this respect, and in Paris and in provincial cities, municipalities and charities have striven in a spirit of emulation to save the lives of young children. Some few years ago a new departure was entered upon by a few Parisian philanthropists. A Madame Coullet was struck by the fact that if expectant and nursing mothers are not well nourished, their offspring must either die prematurely or live, in many instances, diseased in body and mind. Accordingly, Madame Coullet, in 1902, opened a restaurant in one of the poorest quarters of Paris, in which expectant or nursing mothers could procure a satisfactory meal free. The scheme has answered so well that there are now five Coullet restaurants in Paris in which are fed a very large number of women. No questions are asked of an applicant for a meal; it is sufficient that she is an expectant or nursing mother and hungry. Other charitable institutions conducted on somewhat similar lines exist in Paris.

In Great Britain it is only within the past two or three years that any earnest endeavors have been made to cope with the problem of how best to conserve infant life. It is notorious that the inhabitants of the British Isles are in a high degree conservative and hard to move from their old accustomed ways. The question, however, became too serious to be ignored, in fact bade fair to develop into a national menace. Perhaps two-thirds of the British people are dwellers in cities, and urban life is not best calculated to bring forth able and hardy citizens. For infants and young children the conditions in the poorer districts of cities are terrible, and at last it has been brought plainly home to medical men and sanitarians of Great Britain that it is absolutely imperative steps should be taken to save the lives and preserve the health of infants. During the past two years extraordinary activity has been exhibited in that direction in all parts of the country. In many provincial towns, schools for mothers have been inaugurated, and in some towns the example of Madame Coullet in Paris has been closely followed. In London, in one of the large, populous, outlying districts, several restaurants have been established in which expectant and nursing mothers are fed, in which babies are inspected and weighed by a medical man, and advice given in all that concerns the rearing of infants. In two or three other districts similar schemes are in existence, while in one very large and populous quarter situated in the heart of the metropolis, a far more ambitious scheme is now in working order. A charitable society working in cooperation with the borough health board, has inaugurated what is known as a "School for Mothers." A commodious building has been secured at which takes place the following routine of work: (1) Infant consultations. (2) Dinners for nursing mothers. (3) Educative classes. (4) Provident Maternity Club. (5) Home visiting. (6) Fathers' evening conferences. The chief aim of the society is to combat the ignorance that prevails among women of the working class with regard to the rearing of children, and especially to impress upon them the great advantage of breast feeding. It is recognized that if an expectant or nursing mother cannot nourish herself properly the child is not likely to be robust, so in those cases in which the mother is unable through poverty to procure nourishing food, such food is supplied at a nominal cost. The scheme, since its adoption in various parts of Great Britain, is said to have met with great success, and schools for mothers are multiplying in all directions.

THE CAMPAIGN AGAINST TUBERCULOSIS IN SWEDEN.

THE Swedish Committee of the National Tuberculosis Congress has issued a book, dedicated to the Congress, giving in detail an account of the antituberculosis movement in that country. The work, which has been prepared under the editorial supervision of Dr. Sture Carlsson, opens with a most interesting story by Dr. B. Bulire of the origin and work of the Swedish National Tuberculosis Association. The organized campaign against tuberculosis began in 1896 during the annual meeting of the Swedish Medical Society when one session was devoted to a discussion of the subject. One year later three large sanatoria were erected with the proceeds of the Jubilee Sanatorium Fund, amounting to 2,200,000 kr., or over $580,000, created to celebrate the twenty-fifth anniversary of the accession

of King Oscar II to the Swedish throne. In February, 1904, the Swedish National Tuberculosis Association was established and has since been most actively engaged in the struggle against the disease by means of lectures, the publication of leaflets, the collection of statistics, the establishment of sanatoria and hospitals, etc. During the first four years of its existence, 883 popular lectures were given by 38 physicians to audiences aggregating 147,600 persons. A tuberculosis museum was opened in Stockholm in April, 1906, and has been visited by 41,000 persons. The Association publishes a quarterly journal with a circulation of 25,000 copies, and 250,000 copies have been distributed of a pamphlet written for the purpose of combating the widely spread phthisiophobia, the existence of which so greatly increases the difficulty of combating the disease. The government is also assisting in the work, and the Riksdag has made an appropriation of over $100,000 for the year 1909 to assist the communities and associations in the erection of sanatoria, the intention being to renew the appropriation yearly for ten years. The legislature is expected to make a grant to assist in the expense of maintaining the sanatoria and hospitals thus established.

An important detail of the work, described by Dr. G. Neander, is the study of social-hygienic conditions undertaken by the Society. The object of this study is to determine the causes of the spread of tuberculosis within a limited district with a population known to have a high percentage of consumption, and also to endeavor to improve the general hygienic conditions in the community by combined dispensary and sanatorium work and by personal visits of physicians and nurses to the homes of the people.

Among other interesting contributions to the book may be mentioned Dr. E. Wadstein's account of the origin of King Oscar II's Jubilee Fund and of the public sanatoria before spoken of, and Dr. Sture Carlsson's description of other tuberculosis establishments. There are also other articles all treating of the tuberculosis question, and several of a specially scientific character, by Drs. Waller, Tillman, and Friberger, Professors J. E. Johansson, J. Svensson and O. Medin, the Hon. Sv. Palme, Director of the Thule Life Insurance Co., Mr. R. Moosberg, B. A., and Mr. T. Gelhaar, Post-Controller, who gives an account of the Charity stamps issued during the years 1904-08 by the National Association. The translation of the various articles into correct and idiomatic English has been most successfully accomplished. The work will be counted among the most valuable of the contributions to the Tuberculosis Congress, showing, as it does, how in Sweden the campaign against tuberculosis has been begun, and is being carried on, with success. When the limited resources of that country are taken into consideration, the results that have been achieved are worthy of no small praise, and this record of them can but encourage workers in other countries to continue in their warfare against one of the greatest scourges of mankind.

Inhalation of Mercurial Vapor in Syphilis.

The recent advance in our knowledge of syphilis following the discovery of *Spirochæta pallida* and the application of the principles of immunity to this disease has not changed the place occupied by mercury as to the specific drug in the therapy of this affection. On the other hand, the mode of action of the metal is now better understood, it having been shown, for instance, that in the so-called "inunction cures" the absorption of mercury takes place as much or more by the inhalation of the vapor than through the unbroken skin. The discovery of this fact gave origin to several new methods of administering mercury, one of the best being that devised by Kromayer, who employs a mask of soft wire which supports some gauze impregnated with the metal in a state of fine division. Bendig has tried this method in twenty cases of specific disease and reports the results in the *Münchener medizinische Wochenschrift* for September 1, 1908. In every case the effects of the treatment were very quickly obtained, two or three nights of wearing the masks being sufficient to produce a marked repressive effect upon the lesions of the disease; especially good results were obtained with the treatment of syphilitic sore throat of the secondary stage, which is perhaps the most irksome symptom of the disease for the patient and certainly most dangerous to his innocent neighbors. These results were, moreover, obtained without any untoward effects from the inhalation of the metal, only one case of mercurial stomatitis having been observed. Chemical examination of the urine showed that there was a progressive increase in the quantity of the metal absorbed as well as in the amount of the urine excreted by the patient. In Bendig's opinion a regular examination of the urine should be made to forestall the introduction of too much mercury into the organism as well as to recognize in time any untoward effects of the metal upon the kidney. In general the inhalation of mercury proved in many ways superior to the inunction cure. It was certainly less unpleasant to the patient than either the inunction or the injection of mercury, while it possessed the marked advantage of not causing the disturbance of the gastrointestinal tract so common after the internal administration of the metal. These considerations are sufficient to call for a trial of the method in institutions and in private practice, so that further experiences with its application may be reported in the near future.

Ultramicroscopic Examinations.

The principle of ultramicroscopic examination consists in an arrangement of condensors and reflectors which lead to the complete absorption of the central illuminating rays, the lateral rays being at the same time directed upon the field of vision in the microscope; these rays are reflected from every particle in the field of vision and thus bring them out very distinctly. Posner has applied this method of examination to the requirements of clinical pathology and reports satisfactory results in the *Berliner klinische Wochenschrift* for August 3, 1908. Urological pictures were especially distinct; the structures of various urinary crystals could be studied with ease, the composition of the different urinary calculi could be told quite readily, and such formed elements as casts, cylinders, and leucocytes appeared much more distinctly as brilliantly illuminated objects upon a dark background, than with the usual illumination of the Abbé system. One great advantage of the new method consists in its application in teaching, the pictures obtained being very well adapted for demonstration purposes to students whose powers of observation have not been sufficiently developed to perceive many important

details of form and structure in the less distinct pictures of the older system; moreover, the colors of the objects are not changed and the student is taught from the beginning to think of the organized elements of the body in their natural appearance. Dietrich, writing in the same number of the Berlin weekly, discusses the value of the ultramicroscopic examination in hematology. He sees a great advantage in the possibility of momentary registration of various changes in the blood by means of microphotography which the new system affords. The phenomena of hemolysis in various fluids, of morphological changes in diseased conditions, the formation of precipitates in the blood serum, all can be easily observed and permanent records of them obtained with the use of illumination by reflection of the lateral rays. Previous writers have already pictured the very effective appearances obtained in the study of bacteriological objects by ultramicroscopy. It may be safely concluded that this method has come to stay, not indeed to replace the older and well-tried microscopic examinations of stained and unstained objects, but to amplify such examination by introducing new pictures of the same objects seen under different conditions of observation.

Transmissibility of Tuberculosis by Means of Dried Sputum.

The question of the manner of the dissemination of tuberculosis is most important with regard to prophylaxis. The consensus of opinion seems to be that in most cases the infection is air borne, yet a number of experimenters have denied that the bacilli can retain their virulence long after the desiccation of the sputa containing them. Baumgarten, Cadeac, and Mallet made a series of experiments which led them to the belief that this was seldom the method of infection, since the bacilli very soon lost virulence in dry dust. Calmette found that it was difficult to give tuberculosis to animals by causing them to inspire dry infected dust. G. Kuss, on the other hand, writing in the *Bulletin Médical*, for August 5, 1908, gives the details of experiments made by himself which seem to prove that infected sputum is by no means harmless when it has become dry and pulverized. He endeavored to parallel in his experiments on animals the conditions under which people live, examining dust from fabrics that had been dried and then swept, that had been kept in dark corners, etc. The conclusions at which he arrived, after a carefully executed series of experiments, were that sputum under favorable conditions may become dry rapidly, in the course of a few days, and be easily reduced to a fine dust, especially by sweeping. Such dust is extremely virulent when desiccation has occurred rapidly and in darkness. It is easy to infect guinea pigs by making them breathe air filled with dust from sweeping such locations. Such tuberculosis is of the form that is produced by inhalation, and is more severe than tuberculosis caused by inoculation with a quantity of virulent dust. It is anatomically similar to primary infantile tuberculosis. We know that many bacilli, the lactic-acid bacilli, for example, live and preserve their virulence for a long time in dried media, and it is reasonable to assume, independent of experimental proof, that the tubercle bacilli are no less resistant under similar conditions. The experiments of Kuss seem to confirm this assumption, negativing the findings of Baumgarten and Calmette, and to establish the fact definitely that dry infected sputum is to be feared as a source of tuberculosis.

The Bacilli of Bovine Tuberculosis in Human Beings.

During the seven years that have passed since the well known declaration of Robert Koch denying the necessity of any measures to protect human beings from the bacilli of bovine tuberculosis, because of the extreme rarity of the transmission of this disease, the question has been eagerly discussed by numerous investigators throughout the world. Of most value in this connection is the careful study of the frequency of bovine infection, and such a study is published by Karl Steffenhagen in the *Berliner klinische Wochenschrift* for August 17, 1908. This author gives a summary of the findings made in the German Royal Department of Health, altogether one hundred and forty cases of tuberculosis having been investigated. Three patients were found to have suffered from an infection with both types of bacilli, one hundred and seventeen were infected with the human type, and twenty-one patients, all children, suffered from infection with the bacilli of cattle tuberculosis. Of the latter number there were thirteen cases of primary tuberculosis of the intestines and of the mesenteric glands, and six cases of tuberculosis of the cervical glands. The author warns against the use of these figures for estimating the relative frequency of infection with the human and the bovine types of disease because special care was taken to investigate children in whom the site of the disease and the history suggested the possibility of a bovine infection; thus in another series of twenty-seven cases of disease localized in the bones, joints, or meninges only one was due to bovine bacilli. However, it seems certain that in childhood the infection of the gastro-intestinal canal and of the cervical glands with the bovine type of bacilli is much more frequent than Koch's statement would lead one to believe. So far as children are concerned the protection of their food from infection with bovine bacilli is, therefore, imperative, and such protection means for the most part proper measures for obtaining pure milk or rendering suspicious milk harmless. The International Tuberculosis Congress, which is to be in session in Washington the coming week, will probably furnish additional information regarding this matter so full of importance for the welfare of the human race.

Cerebral Rheumatism.

Of all forms of rheumatism attacking other organs than the articulations, cerebral rheumatism seems to be the most rare. It occurs in most cases when the temperature has fallen and the articular manifestations have improved. The attack is characterized by acute delirium, delusions, and insane impulses. In a case reported by Marcel Labbé in the *Tribune Médicale* for July 4, 1908, the patient suddenly disturbed the whole ward during the night by rising, making a noise, and turning the electric lights on and off, ending by chasing all the attendants out of the ward in fear of their lives. He was restrained, and died the following day. In cases of cerebral rheumatism that terminate fatally the brain and meninges are congested and present no other microscopic lesions, but cellular changes are demonstrable. Two cases reported by R. Lépine in the *Lyon Médical* for July 12, 1908, had failed to have efficient salicylate treatment, and the author refers the complication to that fact. Labbé, on the other hand, believes that it generally occurs in alcoholic subjects, who are thus predisposed to cerebral le-

sions. The study of the cerebrospinal fluid does not indicate a preponderance of rheumatic poison in the nervous system. Whether *Bacillus perfringens,* described by Achalme, is the cause of rheumatism is not yet determined, although there have been observations by other authors that seem to support this view. It is an habitual inhabitant of the intestinal canal of man. It is not found in the cerebrospinal fluid, however, in cerebral rheumatism. Whatever the active agent in the disease may be, it must attack an individual predisposed to cerebral lesions, by heredity or acquired nervous condition, in order to affect the cerebrum severely. Lesions of the liver and kidneys are also present to lessen resistance to the effects of the poison.

The Fauna of the Croton Water Supply.

We have been assured from time to time that the water supplied by the city to the boroughs of Manhattan and The Bronx contains no dangerous or even unwholesome matter, and in proof thereof the authorities point to the favorable showing made by the vital statistics of the Board of Health during the past summer. Accepting this statement as correct, we might go further and assert that the water is not only harmless, but even nourishing. Annelid worms, rotifers, small crustaceans, and fairly large gasteropods are far from uncommon visitors in the morning bathtub—also, no doubt, in the midnight drinking-cup. The Croton water was once filtered before distribution, and ran from the taps free from at least the grosser forms of animal life and from the mass of vegetable fibers and organic sediment with which it is now filled. If one were not innocent and free from guile, one might almost be tempted to think—but of course the makers of house filters have no interest in the study of the Croton fauna.

News of the Week.

Tuberculosis Congress Exhibit.—The exhibit planned to precede the opening of the tuberculosis congress was opened to private view on September 19 and to the public on the 21st, in the new National Museum at Washington. The exhibit includes maps and charts showing the extent of the campaign against tuberculosis, the location of dispensaries and hospitals and the methods of treatment. Elaborate displays are also made of window tents, cots, beds, and models of buildings and sanatoria. The congress opens on September 28.

Cholera in Europe and the Philippines.—In St. Petersburg there has been a large increase in the number of cases reported. Up to September 17, 1,278 cases had been reported in the city, of which 365 had been fatal, while throughout Russia the number of cases was 6,747, with 3,130 deaths. Since that time new cases to the number of over four hundred a day have appeared and the mortality percentage has largely increased. The disease has also made its appearance in Berlin in the person of the wife of a Russian state councillor who arrived recently from Peterhof. Several suspects have been taken to the Virchow Hospital for observation. The recrudescence of the disease in the Philippines is causing some uneasiness, but it is thought that the epidemic can be kept under control. Two cases were discovered on the U. S. transport *Sheridan* as it was about to sail from Manila for San Francisco. There has been an average of about fifty cases a day in Manila, but the number of new cases is now decreasing.

Yellow Fever in Havana.—Surgeon-General Wyman of the Marine Hospital Service has ordered the reestablishment of the quarantine against Cuba because of two cases of yellow fever reported from Havana. The cases, which appeared about the middle of September, were the first reported since January 31. It is thought that the patients contracted the disease at the eastern end of the island, where a number of cases have occurred. Yellow fever is also reported from Mexico.

Plague in Ecuador.—Advices from Guayaquil state that the recent epidemic of bubonic plague in that city has been stamped out, the last patient having been discharged from the hospital on September 16. Neither are there any cases of yellow fever in the city at present.

New York Death Rate.—For the week ending September 12 the death rate in New York was again remarkably low. The total number of deaths during the week was 1,219, or a rate of 14.38 per 1,000. In the corresponding week last year there were 1,329 deaths, the rate being 16.18. Of children under five years of age there were 428 deaths during this week in 1908, as against 534 in 1907. The number of births reported during this week was 2,332.

Decrease in Immigration.—Advance figures from the Department of Commerce and Labor show a large decrease in the number of immigrants during the past year. For the month of August, 1908, the total immigration was only 27,782, while in the same month last year the total was 98,825, the figures for the immigration from Russia, one of the countries from which there has usually been the largest flow, was for these months respectively 5,194 and 21,649. During the month of June, 1908, the total immigration from Russia and Finland was 6,280, and the emigration of persons returning to those countries was 5,573, a net gain of 707 only. The immigration from Italy, another country supplying many immigrants, was 3,226 in June, 1908, as against 17,573 in June, 1907. This fall in immigration began soon after the financial panic in the United States in the latter part of last year.

New Hospital for the Insane.—Because of the completion of the new buildings of the Hudson River State Hospital at Poughkeepsie fifty men and 250 women patients from the Kings Park State Hospital and the Central Islip State Hospital for the Insane were transferred to Poughkeepsie on September 16. The patients in charge of nurses and doctors were taken to Long Island City in special cars and thence transferred to a steamer which carried them direct to Poughkeepsie. The opening of these new buildings not only relieves the congestion in the hospitals nearer the city, but allows them to devote more time to the treatment of curable cases.

To Protect the Health of School Children.—The Indiana State Board of Health recently issued a letter to the people with the title, "Why not protect the health of school children?" In this the importance of pure air and proper heating and ventilation is urged, the evils of air starvation are detailed, and the lighting and air supply of schoolrooms are considered.

Examination of School Children.—The physicians of Fargo, N. D., have volunteered to make physical examinations of the school children of that city without cost to the Board of Education or to the pupils. Especial attention will be paid to the eyes, and it is hoped that the physical standard of the children may be greatly improved.

Outings for Nurses.—The pupil nurses of the Mt. Sinai Hospital have been enabled to enjoy the sail up the Hudson through the kindness of Mr. Isaac Stern, president of the hospital and a director in the training school, who has loaned his yacht, the *Virginia,* for these outings.

Almost a Century Old.—Joseph Scofield, a resident of Stamford, Conn., died at his home on September 17, at the age of ninety-nine years and two months. He was born in Lewisboro, N. Y., and had lived in this region all of his life.

Court Orders Amputation.—Because of the opposition of his parents to the operation, surgeons of the County Hospital of Chicago were compelled to obtain an order from the Court directing the amputation of the arm of a fourteen-year-old boy recently. Gangrene following a fracture made the operation necessary, but neither the boy nor his parents would consent.

Old Hospital to Be Burned.—The abandoned isolation hospital belonging to the city of Newark, N. J., is to be burned the next time the wind is favorable. It has been considered unwise to sell the old structures because of the risk of contagion, in spite of disinfection, and the question of how to dispose of them has bothered the city for some time.

Old Ambulance Horse Dead.—After serving but a few weeks less than thirteen years, Ed ly, the oldest ambulance horse attached to Bellevue Hospital, died recently. The old horse had seen many exciting times, for he was on duty when the Windsor Hotel was burned and again at the burning of the Park Avenue Hotel, and carried many patients to the hospital at the time of the accident in the Park avenue tunnel and of the *Slocum* disaster.

Charitable Bequests.—The will of Mrs. Jane A. Townsend, who died last August while in England, provides for the endowment in perpetuity of three beds in the Presbyterian Hospital, New York, in memory of her deceased children. Fifteen thousand dollars is set apart for this purpose. The Presbyterian Home for Aged Women also receives a bequest in this will of $34,500. The will of the late Robert W. Lord gives $2,000 each to the Children's Hospital and to the convalescent home of the hospital and $600 to the Woman's Charity Club Hospital.

St. Agnes Hospital for Crippled and Atypical Children.—The Sisters of St. Francis have established an hospital at White Plains, N. Y., for the treatment of cripples and mental defectives. The property, which was formerly the Westchester County Temporary Home, consists of sixteen acres with modern buildings well adapted for hospital purposes. It will have accommodations for 150 patients and will be supported by voluntary contributions. Applications for admission may be made to Dr. John Carling, 126 East 34th street, New York.

Dr. Julian H. Morris of Dallas, Tex., formerly professor of physiology in the medical department of Southwestern University, has been elected professor of physiology in the medical department of the State University of Oklahoma.

Dr. Jacob Frank of Chicago has donated four hundred volumes to the Columbus Hospital on medical and surgical subjects, in order to provide a reference library for the internes.

Honorary Ph.M. Degrees.—The Philadelphia College of Pharmacy, at the recent graduation exercises, conferred the degree of Master of Pharmacy upon Messrs. Samuel W. Fairchild of New York, Horatio Nelson Fraser of New York, John F. Hancock of Baltimore, S. A. D. Sheppard of Boston, and William McIntyre of Philadelphia.

Gift to John Crerar Library.—The sons of the late Dr. Nicholas Senn have presented to this library more than 2,000 volumes from the library of their father, to be added to the Senn collection.

Fatal Results of the German Army Maneuvers.—It is reported that as a result of the recent German army maneuvers near the western boundary of the empire, 21 soldiers died and 250 were made seriously ill. The men were called upon for excessive physical exertion, in preparation for which there had been no training, and in addition the sanitary service was most inadequate.

The International Stewards' Association in convention in New York during this month discussed at length the pure food laws and urged members to eliminate all traces of adulteration from all products of the earth. Dr. J. J. Leppa of Akron O., suggested the desirability of interstate cooperation to enact a uniform pure food law.

The Association of Military Surgeons of the United States will hold its seventeenth annual meeting at Atlanta, Ga., on October 13 to 16, 1908. The President of the Association is Assistant-Surgeon-General George T. Vaughan, and the Secretary, Major James E. Pilcher of Carlisle, Pa.

The Washington County (Vt.) Medical Society at its annual meeting on September 9, elected the following officers for the ensuing year: *President,* Dr. M. F. McGuire, Montpelier; *Vice-President,* Dr. O. G. Stickney, Barre; *Secretary,* Dr. E. A. Colton, Montpelier; *Treasurer,* Dr. L. A. Rushlow, Randolph.

The Tri-State Medical Society of Iowa, Illinois, and Missouri closed its sixteenth annual meeting at Ottumwa, Ia., on September 9, with the election of the following officers: *President,* Emil Ries, of Chicago; *Vice-President for Iowa,* J. F. Herrick of Ottumwa; *Vice-President for Missouri,* J. E. Chambers of St. Louis; *Vice-President for Illinois,* C. W. Barrett of Chicago; *Secretary,* B. F. Dorsey of Keokuk; *Treasurer,* Emory Lanphear of St. Louis. The next meeting will be held in Quincy, Ill.

The South Dakota State Medical Association in session at Yankton, on September 4, elected the following officers for the coming year: *President,* Dr. S. A. Brown, Sioux Falls; *Vice-President,* Dr. Smiley, Mitchell; *Secretary,* Dr. W. F. Moore, Tyndall; *Treasurer,* Dr. R. D. Alway.

The Missouri Valley Medical Association at its annual meeting in Council Bluffs during the first week of September elected the following officers for the ensuing year: *President,* Dr. C. B. Hardin of Kansas City; *Vice-Presidents,* Drs. A. B. Somers of Omaha and J. M. Bell of St. Joseph; *Treasurer,* Dr. T. B. Lacey of Council Bluffs; *Secretary,* Dr. Charles Wood Fassett of St. Joseph. The next meeting will be held in March, 1909, at St. Joseph.

The Medical Association of the County of Jasper (Miss.) met at Montrose on September 1, and perfected its organization. The following officers were elected: *President,* Dr. J. O. Denson of Bay Springs; *Vice-President,* Dr. G. W. Land of Lauin; *Secretary and Treasurer,* Dr. C. E. Burnheim of Bay Springs.

The Tri-Professional Medical Society of New York held its second annual meeting at the Hotel Astor, New York City, September 15. At the executive session the following officers were elected for the ensuing year: *President,* Dr. J. Monroe Lieberman (reelected); *Vice-Presidents,* Drs. G.

Morgan Muren (reelected) and George B. McAuliffe; *Secretary,* Dr. Walter T. Dannreuther; *Treasurer,* Dr. Daniel E. S. Coleman (reelected).

Obituary Notes.—Dr. Ernest A. Crockett of Lewiston, Me., died at his home on September 3, of typhoid fever, aged 37 years. Dr. Crockett was graduated from Jefferson Medical College in 1896 and had made a special study of diseases of the eye, ear, and throat. He was a member of the staff of the Central Maine Hospital and of the American Medical Association, the Maine Medical Association, and the Maine Eye and Ear Association.

Dr. William Thorne of Covina, Cal., died on September 2, after a short illness, aged 89 years. Dr. Thorne was born in England, but came to this country when fourteen years old. He was graduated from the University of Buffalo in 1850 and had practiced for over fifty years. He was a member of the American Medical Association.

Dr. Solomon S. Landon of Kansas City, Mo., died on September 10, aged 36 years. Dr. Landon suffered a mental breakdown a few months ago owing to the strain of overwork. He was graduated from the Medical School of the University of Kansas in 1896.

Dr. Hermon J. Smith of Lowell, Mass., died at the Lowell Hospital on September 12, from disease of the kidneys, in his seventy-third year. Dr. Smith was a member of the first class graduated from Tufts College, in 1858, and subsequently graduated from the Dartmouth Medical School. For three years he served as army surgeon during the Civil War and was for some years connected with the Lowell Hospital.

Dr. Emmet Porterfield of Indianola, Ia., died suddenly on September 10, of heart disease. He was a graduate of the Bellevue Medical College of New York.

Dr. George Kinney Johnson of Grand Rapids, Mich., died at his home on September 3, after a year's illness, aged 86 years. Dr. Johnson was graduated from the Cleveland University of Medicine and Surgery in 1846 and served as army surgeon during the Civil War. He was a member of the American Medical Association and Chief of Staff and consulting surgeon to Butterworth Hospital.

Dr. William T. Eckley of Grand Haven, Mich., died of heart disease on September 12, aged 53 years. Dr. Eckley was graduated from the School of Medicine of the University of Iowa in 1884, was a member of the American Medical Association and the Chicago Pathological Society, and formerly professor of anatomy in the medical and dental departments of the University of Illinois and Chicago School of Anatomy and Physiology. He retired from professional work about two years ago.

Dr. Alexander Wilder, for some years connected with the New York *Evening Post,* died at his home in Newark, N. J., on September 19, aged 85 years. Dr. Wilder was graduated from Syracuse Medical College in 1850 and also received degrees from the New York Homeopathic College. He soon, however, gave up the practice of medicine for journalism. He had written a number of books and is said to have translated the Bible into six languages.

Dr. John P. Brown, for thirty years superintendent of the Taunton Insane Asylum of Massachusetts, died at his home in Springfield, on September 19, of acute bronchitis, aged 74 years. Dr. Brown was a graduate of the Harvard Medical School and one of the most noted insanity experts in the country.

Dr. Henry G. Gaston of Harvey, Ill., died at his home on August 30, aged 80 years.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE SCIENCE CONGRESS—DR. F. DARWIN'S INAUGURAL ADDRESS—MR. LLOYD GEORGE ON SICKNESS INSURANCE—NOTIFICATION OF INDUSTRIAL DISEASES, OF TUBERCULOSIS—VISIT OF GERMAN DOCTORS—JAMAICA EXPEDITION.

London, Sept. 4, 1908.

This is the week of the British Association for the Advancement of Science, which for the fourth time in its seventy-eight years of existence meets in Dublin. It goes without saying that the Irish capital is keeping up its great reputation for hospitality, and the social side of the great meeting is profusely provided for. At its last visit, 1878, Trinity College could accommodate the association, but to-day more room is needed, and the Royal College of Surgeons, the Royal Dublin Society, the R. T. Academy, the Royal College of Science, and the Royal University have all contributed more or less room for the sections or other proceedings. Over 2,000 members arrived on the first day (Wednesday). Out of respect to the memory of the Earl of Rosse, a vice-president, all proceedings were suspended while his funeral was taking place in the middle of the day. You know that next year's meeting is to be held at Winnipeg. Professor J. J. Thompson has been nominated to preside then.

Invitations from Sheffield and Portsmouth for 1910 and 1911 respectively were received and accepted.

In the evening the president, Dr. Francis Darwin, delivered the inaugural address in the great hall of the Royal University, which was crowded in every corner. He referred casually to the fact that forty years ago another botanist, Sir J. Hooker, was president, and then said he thought the first duty in that position was to speak on subjects to which his own researches contributed. He therefore wished to give a general idea of how changes in environment act as stimuli to plants and compel them to execute certain movements. He said that what is true of such temporary changes of shape is also true of permanent alterations which we call morphological. These two departments of study must be classed together. This leads to the thought that the dim beginnings of habit or unconscious memory found in the movements of plants and animals must be correlated with morphological changes in the development of the adult from the ovum. Connecting thus the phenomena of memory and inheritance, he asked his audience to listen to one more defense of what many of them might consider a lost cause—the doctrine of the inheritance of acquired characters. In illustration he cited sleeping plants; their change is known to be produced by the alernation of day and night. But if put in a dark room after it has gone to sleep such a plant next morning will be seen in the day position and will assume the night one as evening comes on. Here we have what seems to be habit built up by the alternation of day and night—the plant normally dropping its leaves at the stimulus of darkness and raising them at the stimulus of light—and this habit continues in the dark room. The *post hoc* comes to be equivalent to the *propter hoc* in the formation of habit. An illustration from animal life was quoted from Keeble, the *convoluta* which comes to the surface of the sea at the ebb and sinks again as the tide rises. The remarkable fact is that when kept in an aquarium it continues for a short time to perform rhythmic movements in time with the tide. As a human habit he instanced that of a man who goes the same walk every day, turning back at a given milestone; at length he will turn back automatically at the same spot. This is habit; but the point at which he turns is the result of association, and as many would object that in its simplest form association implies a nervous system, the president said it should be remembered that plants have two qualities characteristic of animals—extreme sensitiveness to certain agencies and the power of transmitting stimuli from one part to another of the plant body. To the objection that association implies consciousness, he said it was not possible to know whether plants had it or not. Its possession as a faint copy was consistent with the doctrine of the continuity of all living things. As regards reaction to environment, he claimed that a plant and a man must be placed in the same class in spite of the fact that as regards complexity of behavior the difference is so enormous. He then contrasted his theory with the views of Weissmann on heredity, holding that it was strong where those were weakest.

It is not often that a cabinet minister interests himself in medical subjects, so perhaps one should make the most of an interview granted last week by Mr. Lloyd George, Chancellor of the Exchequer, on his return from Germany. He declared the provision for sickness in connection with the German pensions plan to be "far and away the most remarkable part of that scheme," and pointed out that the sick funds are administered by a joint committee of workmen and employers and the "State does not contribute a penny towards sickness, but it is all compulsory; workmen and employers must contribute, and this extends even to domestic servants." A part of the plan which he considered most beneficent was that providing for the erection of sanatoria, especially for lung cases. In view of the Chancellor's impressions and the awakening of the public press since the King and royal family evinced their deep interest in the campaign against tuberculosis, attention is again being called to Dr. Bulstrode's valuable report to the Local Government Board. I have referred to this more than once, but as it is now obtaining more notice some of the particulars may not appear belated. By means of the far-reaching system of compulsory insurance against sickness and incapacity the German workman attacked by tuberculosis has a legal claim for treatment and maintenance, as well as support for his family. Thus he can avail himself of this provision at the outset of his attack and it is recognized that the earlier the disease is diagnosed the better are his prospects. In connection with invalidity insurance, nearly £9,000,000 has been employed in the construction of hospitals, sanatoria, convalescent institutions, and pensions.

Very few of the numerous establishments founded to provide for tuberculous workpeople would have existed if insurance institutions had not provided funds. As tuberculosis is very largely a disease of the working classes, the insurance system opens to them advantages which formerly were beyond their means, relieving them of their financial difficulties, removing their occupational disabilities, and thereby exerting a favorable influence as regards both the prevention and cure of the disease. It is therefore not at all remarkable for a cabinet minister who looks into the subject to be impressed with its importance. Some quidnuncs are asking if Mr. Lloyd George is fearing that the Government made a mistake in trying the non-contributory pension scheme. But he scarcely gave the interviewers a glimpse into his mind on the matter and a speculation of the kind is not appropriate to a medical journal.

Notification in some form or other is a question pretty sure to crop up wherever a goodly number of medical men assemble. So at Sheffield it was brought forward by Dr. Alex. Scott of Glasgow, who is a thorough-going advocate of this measure. He had a paper in which he urged the compulsory notification of all industrial diseases, whether arising from the nature of the patient's employment or from accident. Of course the question of compensation was often involved, but that was not his chief point—which was rather that early intimation of outbreaks of disease would be obtained, the sufferers would get early treatment, and certain accidents would be prevented. Further, it would promote cleanliness among workers and show them the importance of sanitary precautions. He instanced various neuroses, cardiac affections, and other diseases which were so often due directly to occupation. Fibrosis of the lung due to dust had been carefully investigated by a department commission, but was not scheduled in the compensation act. In his sanatorium 40 per cent. of the beds were occupied by cases of miner's phthisis, though tubercle bacilli were not detected in about 33 per cent.

Dr. Alcock pointed out the difficulty as to persons who had a tendency to some disease which would probably develop when they began work, and asked if they were to be compensated like healthy men. If so, masters would insist on rigorous examination and refuse them work.

Dr. Mechan wanted to know where notification was to stop. It was held by some notificationists, and the contention had been upheld by courts, that a man with chronic cardiac disease who died when employed should be compensated by the employer. What a prospect for him! In eleven years the sums paid for compensation had increased 200 per cent.

Dr. Legge said Dr. Scott was, as usual, ahead of the time, and at present the goal to which he pointed was unattainable. Perhaps when insurance became universal his interesting proposals might be found possible.

Dr. Scott replied that he advocated early examination, which he held would decrease, not increase, compensation. Notification should be made first of all to the patient, then the employer should receive a friendly word, which would often enable him to change the sufferer's work and so very often save his life.

In the Public Health Section there was a discussion on phthisis in which both compulsory notification and the provision of sanatoria for poor patients were advocated. It was opened by Dr. Alex. Walker of Edinburgh, who regarded phthisis as emphatically a poor person's disease. It was among those who were fed, clothed, and housed badly that the power of resistance was at the lowest. This class did not comprise merely the pauper or the legally poor, but numerous worthy persons with small earnings and hard, unhealthy toil, whose industry and frugality often helped to make them an easy prey to the disease. The immense majority of cases occurred in low rented houses. The air of our cities was impregnated with the microbe in its dried state, which is the most dangerous, not to say irresistible. Between the ages of 15 and 50 phthisis was the cause of 30 per cent. of the mortality from all causes. This would indicate that 200,000 persons were to be found in various stages of the disease and at least one-fourth of them would be in the early stages, and 40,000 would be poor. For this army we have only thirty-five sanatoria with 15,000 beds and accommodation for about 6,000 patients per annum.

The amount of money required must be large, but Dr. Walker did not countenance extravagance—rather he urged the necessity of "setting our faces like flint against the besetting temptation of these enterprises." The first sanatoria were built for rich people, but palatial buildings were not needed for the poor. Dr. Walker quoted cases running up to £750 per bed, which he pronounced disgraceful. Others had only amounted to £80 or £90 per bed. The results had no relation to the cost. If anything the cheaper had been the more efficient. If the money already spent had been well spent, it would have provided beds capable of accommodating 20,000 patients.

Dr. Niven of Manchester, who followed, described the measures adopted in that city, where compulsory notification is established. As soon as a case is reported, disinfection is carried out, and instructions given as to expectoration and other matters. He said tuberculosis at birth was very rare. The majority of persons were free from the disease or hereditary predisposition until exposed to infection. The conception of tuberculosis contracted from milk in infancy and remaining latent might be dismissed. He did not deny the possibility, but the number of such cases must be small compared with those who contracted the disease in adult life. It was more and more evidently a pauperizing disease. It was essential to afford aid to consumptive families, but the condition must be notification and obedience to instructions.

Sir Charles Cuffe argued that there was no chance of stamping out phthisis unless notification was enforced.

Dr. McWalter opposed, as although sanatorium treatment was desirable it was too costly. People who spent £800 a bed on buildings deserved to be shot. One of the greatest misfortunes to consumptives was the discovery of the bacillus, but for which we should be treating them rationally, for they were beginning to see that the organism was not the only cause.

Dr. Walker thought the last speaker rather reactionary and Dr. Squire suggested passing a resolution in favor of compulsory universal notification. The proposal was dropped, as Dr. McWalter opposed it.

Dr. Brown of Ayr feared notification would interfere too much with the lives of people and insurance questions might arise.

Dr. Wilson of Lanark testified to good results of compulsion in his district. They were not going to stamp out the disease, but the work was beneficial and on right lines.

Dr. Scurfield favored compulsion and in Sheffield it had caused no difficulties. Hospital accommodation ought to be provided, too.

Sir Alfred Jones, chairman of the Liverpool Tropical School of Medicine, is organizing an expedition to Jamaica to investigate the insect life and the diseases of the island. Mr. R. Newstead, lecturer on entomology and parasitology at the school, will leave in November and will be accompanied by a medical expert.

Yesterday 350 German doctors came on a visit to the Isle of Wight. They landed at Ryde, and after inspecting the Royal County Hospital went by train to Ventnor, where the streets were decorated in their honor and they were received by the municipal authorities. They visited other establishments. At the Royal Na-

tional Home for Consumption they were welcomed by the medical staff and committee, and the senior physician, Dr. Robertson, gave an address on the treatment carried out in the institution. Luncheon was provided in the pavilion, after which Professor Rosin gave an address on seasickness. A lecture was delivered in the town hall by Lieutenant Damant, R.N., on caisson disease. The visitors also went to Osborne.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

CHOLERA—SPREAD OF THE DISEASE BY BACILLI CARRIERS—SANITATION OF THE ISLANDS—GOOD RESULTS BEGINNING TO BE MANIFEST.

MANILA, July 29, 1908.

CHOLERA, of which mention has heretofore been made, still continues its onward march, although the number of cases has not been materially increased. As the disease appears in new provinces it is gradually disappearing in the provinces in which it first appeared.

From January 1, 1908, to the present time there have been 8,599 cases and 5,401 deaths reported. Of this number there occurred in Benguet 8 cases and 4 deaths; Bulacan, 115 cases and 8 deaths; Misamis, 606 cases and 201 deaths; Nueva Ecija, 295 cases and 236 deaths; Pampanga, 177 cases and 155 deaths; Pangasinan, 5,334 cases and 3,176 deaths; Capiz, 766 cases and 571 deaths; Ilocos Sur, 415 cases and 316 deaths; Iloilo, 18 cases and 13 deaths; Laguna, 4 cases and 3 deaths; Nueva Vizcaya, 6 cases and 6 deaths; Rizal, 169 cases and 139 deaths; Tarlac, 149 cases and 103 deaths; Union, 244 cases and 180 deaths; scattered in various provinces, 293 cases and 213 deaths. Within the past week the disease has been carried from Capiz province over the mountains into Iloilo province and has now made its appearance in Jaro and Santa Barbara.

Undoubted evidence has been obtained that certain persons in Manila are "cholera carriers," one such individual being now isolated in San Lazaro Hospital who is apparently in perfect health but whose stools contain the spirilla of Koch.

In view of the criticisms which have been made from time to time with regard to the unsatisfactory sanitary condition of a large part of the towns throughout the Philippine Islands, it may be of interest to note the following statement taken from the report of the Director of Health for the fiscal year ended June 30, 1908: "The efforts of the bureau during the year were directed more and more toward the laying of a sound foundation upon which to erect a sanitary superstructure that will endure. The efforts of the earlier years of modern health work in the Philippines were necessarily restricted to battling with actual outbreaks of great devastating diseases like cholera, plague, and smallpox, rather than with the conditions which made these diseases possible. In other words, symptoms had to be treated rather than causes. Persons actually suffering with cholera had to be cared for rather than to install a permanent system of water supply which would make a cholera outbreak impossible at a later day. The resources of the islands are such at present that greater sums than those set aside during the past few years are not available. It has, therefore, become the policy of the bureau to take each peso that becomes available for health work and vaccinate, say, forty people with it, thus protecting them against smallpox; or free a certain number of individuals of intestinal parasites, thus saving them from many other diseases; or invest it with others in artesian wells, rather than to use it for sweeping sidewalks, penning up pigs, or cleaning back yards. All of these latter measures are highly desirable, but when there is only sufficient money to accomplish every needful thing it would seem that there is but one course to pursue, and that is to invest it in those things which will give the greatest permanent result."

This policy has given rise to considerable adverse criticism, which time only can counteract. In the future the permanent results will speak for themselves. The achievements of the reduction in the number of cases of smallpox and leprosy, and the lowered mortality where artesian wells are in use, are already beginning to attract attention, and will soon demonstrate the superiority of this new departure over the old empirical "clean-up" policy.

Briefly, then, it is believed that the direct road to the goal of a permanent low morbidity and mortality rate in the Philippine Islands is through improved water supplies, vaccination, elimination of intestinal parasites, systematic warfare against tubercle bacilli, the eradication of the malarial mosquitos, and through improved hygiene to combat infant mortality.

A PLEA FOR ESPERANTO.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—As a student of Greek from both the literary and philological points of view, and as one who by more or less assiduous application has obtained the pleasure of being able to enjoy the grandeur of Æschylus and the glories of Pindar, I am much interested in the proposition in the MEDICAL RECORD of August 15, concerning the possibilities of Greek as a world language. As is noted in this discussion, the suggestion of Modern Greek as a second tongue for all the nations of the civilized world is not novel, and Greek has the advantage of being more of a neutral language than is English, German, or any other language spoken by a people politically and commercially prominent, the adoption of whose tongue as a world language is out of the question on account of racial jealousy.

But there are certain practical difficulties in the way of Modern Greek as an international language. Even though a language of great difficulty may be easily acquired in one's infancy, the fact remains that no child can acquire any language unless it hears this language spoken. That is to say, a prerequisite of either teachers or relatives who know the language well is necessary for the child's learning it. Therefore the international language must be sufficiently easy to learn that for a few generations at least, or until it has already become completely international, adults may be able to master it well enough to teach it.

Even admitting that Modern Greek is less difficult than French or German, it is not so easy that our teachers can promptly acquire a complete and accurate knowledge of it, and be intelligible if "its use were continued in the school curriculum in the teaching of History and of Physics, Chemstry, and the other scientific branches." There exists no national language whose mastery to such a point does not demand years of careful study, and the swiftness with which one may obtain a smattering of such a language, and "enough to get along with" has nothing to do with really learning the language. Yet the contention for Greek is only that "if it were taught in all the elementary schools of the world as a living tongue, not as an exercise for translation merely, the coming generation would use it as fluently and naturally as it would the national speech."

Shall we, then, import native Greeks to teach their language? Even if this were at all possible on the wholesale scale necessary, it would mean the wiping out of Greece as a European nation, for we should need all and more than all of the two million or so Greeks as instructors in the United States alone, assuming even then that one Greek could teach his tongue to forty Americans; and if we could not leave any Greeks in Europe to teach Greek to the Europeans, leaving out of the question now the Japanese and other Asiatic peoples, the newly acquired language would not be of as much practical value as English itself.

We must, then, have an international language that shall be easy of complete acquirement, if it is to be really an international language. Esperanto, as admitted, is easy. It is a living language, for it is already spoken by several hundred thousand people, although it is still in its infancy. How many people will be speaking it in but a year from to-day can be estimated only by noting with what speed the ranks of its followers are constantly increasing. It has a rapidly growing literature, consisting of far more than "a few translations and ephemeral articles." And, most important of all, it can be taught to the coming generation, for the adult population is learning it first, not in one spot alone, but in North and South America, in Europe, in Japan and India, and the Philippines, and in Greece, too. The originally small number of Esperantists in all these regions is increasing, and they are not merely theorists and dreamers, but really become masters of the language.

They can do so because its grammar is simple, logical and regular, and fifty times as easy as that of Latin, English, German, French, or Greek. Its vocabulary was not arbitrarily created, but the great majority of its words are already familiar to Europeans and Americans. The sounds and pronunciation are international, and so simple that persons of different race and language can readily and promptly converse in Esperanto, after having learned the language from books alone. And no better way of testing this last statement can be suggested to the doubter than that he learn a little Esperanto, and then attend the Fifth International Congress of Esperantists at Chautauqua, N. Y., next August, and see for himself.

IVY KELLERMAN, Ph.D.

175 WEST ELEVENTH AVENUE, COLUMBUS, OHIO.

AN IMPOSTOR.

To the Editor of the Medical Record:

Sir:—I wish to warn the profession against a colored man who represents himself as authorized to collect money for the Colored Aged Home of Irvington, N. J. I wrote to the Home to inquire about this man, and was informed that they have no collector in New York. I would suggest that any physician on whom he may call would do well either to call up 3100 Spring and give him in charge, or else to get his name and address, and then notify the Home, writing to John H. Williams, 57 Brunswick street, Newark, N. J. He was about middle age, rather slight, moderately tall, reasonably well dressed in dark suit, wore a moustache, but, I think, no beard. He carries a notebook, in which, I am sorry to say, will be found my name as a contributor. He has also several letters, one, I think, purporting to be from the Mayor of Newark.

Will somebody kindly catch him? I will be glad to appear against him.

Forbes R. McCrery, M.D.

123 East Fortieth Street, New York.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 10, 1908.

Primary Carcinoma of the Appendix.—C. O. Kepler reports one case where patient was a woman of 43 years who some five years before had had an abdominal tumor removed, but whose present illness followed a series of attacks of right iliac pains with irregular vomiting. A diagnosis of appendicitis was made, and after some delay operation was performed. It was found that the appendix was the seat of a primary carcinoma. Microscopic examination showed submucosa and mucosa replaced by a young connective tissue in which were set alveolar masses of an epithelial new growth. Alveoli were in places large, generally small, and showed here and there attempts at gland formation. The new growth had involved the circular layer of muscle which was in places almost wholly replaced. The longitudinal layer of muscle was deeply infiltrated with new growth which had spread widely in the subperitoneal connective tissue. Infiltration of the tissues with lymphoid and plasma cells was general and marked. The authors refer to the papers of Elting and Rolleston and Jones, whose conclusions are quoted in full.

Omentopexy to the Intestine Deprived of Its Mesentery.—C. L. Scudder reviews the work of various surgeons along the line indicated, and records the results of experiments upon dogs, noting the behavior of the bowel after being shorn of its mesentery and dependent for its blood supply on the omentum. He regards the procedure of omentopexy to the gut thus deprived of the mesentery as of very limited use in surgery. He regards resection and anastomosis of the bowel as the preferable course following a removal, accidental or intentional, of the mesentery from the bowel. It is conceivable that an omentopexy might prevent necrosis of the bowel if a limited portion of intestine (2 or 3 cm.) were deprived of its mesentery. The value of an omentopexy to the bowel would be increased if a plastic of omentum were made to either side of the denuded area. Experiments were made upon four dogs to determine the result of detaching the mesentery from a measured length of gut and replacing the detached mesentery by omentum, and it was shown that in this animal if the vessels in the mesentery are tied far from the mesenteric attachment, the gut remains viable even when considerable mesentery is detached. The nearer to the gut the ligation is made of the mesenteric vessels, the less detachment of mesentery can be made and viable gut remain. From 16 to 20 centimeters of gut may be denuded with subsequent omentopexy safely. Ten centimeters may be denuded with omentopexy, with gangrene. In the instances which recovered after two denudations and two omentopexies, the gut at the seat of operation was slightly smaller in size and a little thicker from edema.

New York Medical Journal, September 12, 1908.

Jaundice Due to Disease of the Biliary and Pancreatic Passages.—This subject is considered by J. J. Gilbride, who reports one case of cancer of the pancreas in which there was an absence of hydrochloric acid and pepsin from the stomach contents. Under the general title of the paper, nothing particularly new is presented. His own patient was a man of 52 years, whose symptoms had begun some four months before he came under observation and consisted of fullness and weight in the abdomen after eating, with belching and enlargement of the abdomen. Jaundice was present. A diagnosis was made of cancer of the liver with obstruction of the common or hepatic duct. The fact that the stools were clay colored and very offensive suggested that the pancreas might be also affected. The stomach contents showed absence of free HCl and pepsin. No lactic acid was present or no Oppler-Boas bacilli. The patient grew progressively worse and died after an illness of about five months. The autopsy showed a moderate amount of free fluid in the abdomen. There was a cancer of the pancreas and liver with involvement of right free border of lesser omentum. The glands along the common duct formed a chain of hard nodules. The stomach and intestines were normal. There were no gallstones. The gallbladder was distended, but healthy in appearance. The primary growth was in the pancreas. The pleurisy in this case was due to involvement of the diaphragm, and the attacks of cramp-like pain resembling those of biliary colic were probably due to pressure from without upon the common duct, as attacks of this kind are occasionally met with when the common duct is pressed upon from without.
